THE wonderful bore of five miles through the Hoosac Mountains goes forward with persistent steadiness, and bids fair to be an accomplished fact in 1874, as promised by the contractors. Some conception of the magnitude of this great work may be formed when it is known that at the west end the workmen have fully one-third of a mile of solid mountain above their heads.

A ZOOLOGICAL Garden in Central Park, New York, has been objected to on the following grounds:—The defect of the Central Park is a lack of breadth and repose. This defect grows out of the natural limitations fixed by the original rocky surface of its site, and from the necessity of providing structurally for the convenience and safety of great throngs of people in a public pleasure-ground that is expected finally to be situated in the heart of a densely populated city. The impracticability of making, in either section of the Park, open spaces of greensward as large as desirable was recognised from the outset, but as much as possible was done to gain ground in this direction, and the central meadow stretches are the result in the upper Park. They supply two connected spaces, each about a quarter of a mile in extent, partially separated by a mass of rock and almost completely surrounded by a border of indigenous trees, which are already beginning to take on umbrageous forms and to cast broad shadows over the now well-established turf. These meadows constitute the only broad space of quiet rural ground on the island which has been left undisturbed by artificial objects, and much labour has been expended to render practicable the preservation of their present general character. A Zoological Garden must be made up to a considerable extent, if not altogether, of small scattered buildings and small fenced yards; it requires little breadth or unity of surface in its site, and it must be adapted to recreation of a completely diverse character from that which this ground has been prepared to serve.

THE busy town of Sheffield, we are glad to see, is waking up to a sense of its position as one of the industrial centres of England. A meeting was recently held to consider the propriety of presenting the Museum of the Literary and Philosophical Society to the town, on condition that a Free Public Museum be established by the Town Council, and a suitable building be erected. The President of the Society, Mr. H. C. Sorby, occupied the chair, and briefly opened the meeting. The Master Cutler, Mr. W. Bragge, then rose and proposed the following resolution, "That upon the establishment by the Town Council of Sheffield of a Free Public Museum and the provision of such accommodation for it as the Council of the Literary and Philosophical Society shall deem suitable, the said Society hereby authorises its Council to transfer to the said Free Public Museum its collections of specimens illustrating natural history, geology, mineralogy, antiquities, numismatics, ethnology, and industrial art, and also such apparatus as is of historical interest, together with the cases containing the said articles, but not its library nor modern scientific apparatus." After some discussion, the resolution was put to the meeting and carried unanimously.

DR. COBBOLD describes, in the *British Medical Journal*, an Entozoön which, if not actually, is practically unknown to the most experienced helminthologists. The *Stephanurus dentatus* s a species of Strongylus which has hitherto been described only by the late Professor Diesing of Vienna in the *Annalen des Wiener Museums*, a scarce book to obtain. It is not fully described in any of the systematic works, and appears never to have been seen by Kuchenmeister or Von Siebold. The interest of this observation consists less in the ready identification of the parasite by Dr. Cobbold, than in the abundance with which, according to Dr. Fletcher of Indianopolis, who forwards the specimen for examination, it is found in the hogs slaughtered in that part of the world. The bearing of this observation on the extension of parasitic disease remains yet to be determined. The suggestions arising out of Dr. Cobbold's observation will, no doubt, be followed out by local inquirers; and we shall expect to hear more of this hitherto rare, and probably interesting, stranger.

AT a recent meeting of the Scientific Committee of the Royal Horticultural Society, Mr. Alfred Smee exhibited some lemons from Sicily attacked by a species of coccus, quite distinct from the well-known coccus of the orange, and apparently an undescribed species. It was stated that nearly the whole of the lemon-crop in Sicily is attacked by this parasite, which renders it almost valueless for the English market. Although the juice is not much affected, the skin is completely spoilt and rendered uncrystallisable; by far the most important use of lemons in this country being of the rind for use by confectioners. The root appears to be at the same time attacked by a fungus.

AT the close of 1870 the numbers of the several classes belonging to the Institution of Civil Engineers were:—16 honorary members, 709 members, 1,010 associates, and 201 students, together 1,936, as against 1,802 at the same date last year, showing an increase at the rate of $7\frac{1}{2}$ per cent. in the twelve months.

IN analysing the statistics of inquests held as Coroner of Central Middlesex, Dr. Lankester points out, in his seventh annual report just prepared, that the proportion of suicides to the population in England and Wales is 1 in 12,000 of the population, while the proportion in Central Middlesex is about 1 in 13,000 of the population. The figures seem to show that of all causes of death suicide is the most constant. The proportion in which the sexes commit suicide is nearly everywhere the same. It may be stated that the proportion of males to females is as five to two. The ages at which suicide is committed are for the seven years nearly the same. One in twelve are young people under 20 years of age; a larger proportion amongst people above 60; and the remainder, four-fifths of the whole, are equally divided amongst people from 20 to 40 years of age. A further analysis of the cases shows that, as a rule, women prefer taking poison and drowning themselves. Of the twenty-three cases of female suicide in 1868-9, six were from poison and ten from drowning. Women seldom cut their throats or hang themselves, whilst, of the sixty-six cases of male suicide, exactly half chose these methods of self-destruction. Men are also more given to jumping out of windows and from the tops of high places.

AN admirable paper on "The Food and Habits of Beetles," by Mr. Townend Glover, appears in a recent report of the Commissioner of Agriculture for Washington. It contains brief descriptions of the beetles which are injurious to vegetable or animal substances, with their common and scientific names, and nearly 200 figures, roughly but characteristically executed. An alphabetical list of the principal substances frequented by beetles is given at the end, with cross references to the first part of the paper.

THE Winchester and Hampshire Scientific and Literary Society, which was formed in 1869, has issued its first report. From this we learn that over 100 members have joined, and that the meetings are frequent and well attended. The papers are not confined to subjects connected with natural history, but embrace archæology and kindred topics. There is a botanical section, of which Mr. Frederick J. Warner is secretary; and we gather from the report that a flora of Winchester is in contemplation. It is perhaps not too much to hope that, with the aid of the Newbury Club, a complete flora of Hampshire may be undertaken by the society. The President is the Rev. C. A. Johns, Mr. A. Angell, jun., acting as the hon. secretary. The meetings are held on the second Monday of each month. The annual subscription is 10*s*.

THE *Scottish Naturalist* states that a work on the Birds of Scotland, by Mr. Robert Gray, Secretary to the Glasgow Natural History Society, is in the press; and that Mr. Howie, Secretary of the Largo Naturalists' Field Club, is drawing up, for publication, a catalogue of the plants of Fifeshire.

A JOURNAL is published in Liverpool, under the title ot "Cope's Tobacco Plant, a Monthly Periodical, interesting to the Manufacturer, the Dealer, and the Smoker," from the January number of which we quote the following:—"Huxley and Friends—Attention! An American exchange says:—'Professor Huxley may become a good Christian yet; he smokes now, after forty years' hostility to tobacco.' Now, at cost of losing ground for ourselves, we ask Professor Huxley and his friends—Will they admit that the distinguished gentleman was not a Christian during those forty years when he abstained from tobacco? And that the first step towards his salvation was—smoke? We expect an answer; because, should we be in danger of yielding to the arguments of zealous anti-tobaccoites, we might fall back upon that most infallible of argument-stoppers, the religious sentiment."

A LETTER in the *Gardener's Magazine*, which has just come to our notice, imputes a grave charge of false teaching to the authorities of the South Kensington Museum. The writer says:—"In the Educational Series is a large glass case of British butterflies, conspicuously labelled 'The Gardener's Foes.' The case contains forty-three out of the sixty-six native species. Now, the idea of all these, or even the majority of them, being injurious, is most absurd, and tends to perpetuate erroneous notions, and to exterminate these beautiful creatures from the land." Then follows an enumeration of the species exhibited, and the names of the plants upon which, according to the writer, the insects actually feed, most of them being roadside weeds. We draw attention to this in order that "erroneous notions," on whichever side they may be, may *not* be "perpetuated."

GOLD ore having been discovered in Madagascar, the Government of the island has prohibited the search. If gold is discovered in remunerative quantities, there will be such a rush of Europeans to the country as will dispossess the native inhabitants.

THE African diamond fields are being overdone; they have become the seat of an extensive population. A little canvas town has rapidly sprung up on the banks of the Vaal River. Stores have been opened, the rival proprietors of which advertise their wares in a newspaper devoted to the diamond interest, and printed on the field; and, finally, a music-hall has been started for the amusement of the thousands of diggers, who with their wives and children are now encamped in the "happy valley."

SCIENCE IN AMERICA

THE following appropriations by the U.S. Congress were made at the session of 1869-70 for the ensuing year, July 1, 1870, to June 30, 1871, in aid of Science, Literature, &c.

It should be observed that the undermentioned appropriations are those of the General Government, and not those of the separate States, which, in the aggregate, would far exceed the amount here presented.

THE INFLUENCE OF INTENSE COLD ON STEEL AND IRON

THERE has recently been a most interesting discussion at the Literary and Philosophical Society, Manchester, on the above subject, the result of which seems to be that we must at once give up the idea that such accidents as the one, for instance, near Hatfield, are due to anything beyond the control of the Railway Companies concerned.

The paper which gave rise to the discussion was by Mr. Brockbank, who detailed many experiments, and ended by stating his opinion that iron does become much weaker, both in its cast and wrought state, under the influence of low temperature; but Mr. Brockbank's paper was immediately followed by others by Sir W. Fairbairn, Dr. Joule, and Mr. Spence, which at once put an entirely new complexion on the matter.

As Dr. Joule's results are the most to the point we may take them first. He says:—

"As is usual in a severe frost, we have recently heard of many severe accidents consequent upon the fracture of the tires of the wheels of railway carriages. The common-sense explanation of these accidents is, that the ground being harder than usual, the metal with which it is brought into contact is more severely tried than in ordinary circumstances. In order apparently to excuse certain Railway Companies, a pretence has been set up that iron and steel become brittle at a low temperature. This pretence, although put forth in defiance, not only of all we know of the properties of materials, but also of the experience of everyday life, has yet obtained the credence of so many people that I thought it would be useful to make the following simple experiments:—

"1st. A freezing mixture of salt and snow was placed on a table. Wires of steel and of iron were stretched so that a part of them was in contact with the freezing mixture, and another part out of it. In every case I tried the wire broke outside of the mixture, showing that it was weaker at 50° F. than at about 12° F.

"2nd. I took twelve darning needles of good quality, 3in. long, $\frac{1}{24}$in. thick. The ends of these were placed against steel props, $2\frac{1}{3}$in. asunder. In making an experiment, a wire was fastened to the middle of a needle, the other end being attached to a spring weighing-machine. This was then pulled until the needle gave way. Six of the needles, taken at random, were tried at a temperature of 55° F., and the remaining six in a freezing mixture which brought down their temperature to 12° F. The results were as follow:—

Warm Needles.	Cold Needles.
64 oz. broke	55 oz. broke
65 " "	64 " "
55 " "	72 " "
62 " "	60 " bent
44 " "	68 " broke
60 " bent	40 " "
Average $58\frac{1}{3}$	Average $59\frac{5}{6}$

"I did not notice any perceptible difference in the perfection of elasticity in the two sets of needles. The result, as far as it goes, is in favour of the cold metal.

"3rd. The above are doubtless decisive of the question at issue. But as it might be alleged that the violence to which a railway wheel is subjected is more akin to a blow than a steady pull; and as, moreover, the pretended brittleness is attributed more to cast-iron than any other description of the metal, I have made yet another kind of experiment. I got a quantity of cast-iron garden nails, an inch and a quarter long and ⅛in. thick in the middle. These I weighed, and selected such as were nearly of the same weight. I then arranged matters so that by removing a prop I could cause the blunt edge of a steel chisel, weighted to 4lb. 2oz., to fall from a given height upon the middle of the nail as it was supported from each end, $1\frac{1}{16}$in. asunder. In order to secure the absolute fairness of the trials the nails were taken at random, and an experiment with a cold nail was always alternated with one at the ordinary temperature. The nails to be cooled were placed in a mixture of salt and snow, from which they were removed and struck with the hammer in less than 5^s."

The collective result of the experiments, the details of which need not be given, was that 21 cold nails broke and 20 warm ones.

Dr. Joule adds, "The experiments of Lavoisier and Laplace, of Smeaton, of Dulong and Petit, and of Troughton, conspire in giving a less expansion by heat to steel than iron, especially if the former is in an untempered state. Such specimens of steel-wire and of watch-spring as I possess expand less than iron. But this, as Sir W. Fairbairn observed to me, would in certain limits have the effect of strengthening rather than of weakening an iron wheel with a tire of steel.

"The general conclusion is this: Frost does *not* make either iron (cast or wrought) or steel brittle, and that accidents arise from the neglect of the companies to submit wheels, axles, and all other parts of their rolling stock to a practical and sufficient test before using them."

Mr. Spence in his experiments decided on having some lengths of cast-iron made of a uniform thickness of ½in. square, from the same metal and the same mould.

He writes:—"Two of the four castings I got seemed to be good ones, and I got the surface taken off, and made them as regular a thickness as was practicable.

"I then fixed two knife-edged wedges upon the surface of a plank, at exactly nine inches distance from each other, with an opening in the plank in the intervening space, the bar being laid across the wedges, a knife-edged hook was hung in the middle of the suspended piece of the bar, to the hook was hung a large scale on which to place weights.

"The bar was tried first at a temperature of 60° F.; to find the breaking weight I placed 56lb. weights one after another on the scale, and when the ninth was put on the bar snapped. This was the only unsatisfactory experiment, as 14 or 28lb. might have done it, but I include it among the others. I now adopted another precaution, by placing the one end of the plank on a fixed point and the other end on to a screw-jack, by raising which I could, without any vibration, bring the weight to bear upon the bar. By this means, small weights up to 7lb. could be put on while hanging, but when these had to be taken off and a large weight put on, the scale was lowered to the rest, and again raised after the change was made. I may here state that a curious circumstance occurred twice, which seems to indicate that mere raising of the weight, without the slightest apparent vibration, was equal in effect to an additional weight. 3¾cwts. were on the scale, a 14lb. weight was added, then 7lb., then 4lb, 2lb., 1lb., and 1lb., making 4cwts. and 1lb. This was allowed to act for from one to two minutes, and then lowered to take off the small weights, and replaced by a 56lb., intending to add small weights when suspended, raised so imperceptibly by the screw, that the only way of ascertaining that it was suspended was by looking under the scale to see that it was clear of the rest. As soon as it was half-an-inch clear it snapped, thus breaking at once with one pound less than it resisted for nearly two minutes.

"Six experiments were carefully conducted at 60° F., the parts of the bars being selected so as to give to each set of experiments similar portions of both bars; the results are marked on the pieces. My assistant now prepared a refrigerating mixture which stood at zero, and the bars were immersed for some time in this, and we prepared for the breaking trials to be made as quickly as could be, consistently with accuracy, and to secure the low temperature each bar on being placed in the machine had its surface at top covered with the freezing mixture. *The bars at zero broke with more regularity than at* 60°, *but instead of the results confirming the general impression as to cold rendering iron more brittle, they are calculated to substantiate an exactly opposite idea, namely, that reduction of temperature*, cæteris paribus, *increases the strength of cast iron.* The only doubtful experiment of the whole twelve is the first, and as it stands much the highest, the probability is that it should be lower; yet, even taking it as it stands, the average of the six experiments at 60° F. gives 4cwt. 4lb. as the breaking weight of the bar at that temperature, while the average of the six experiments at zero gives 4cwt. 20lb. as the breaking weight of the bar at zero, being an increase of strength from the reduction of temperature equal to 3·5 per cent."

Sir W. Fairbairn's evidence is of great importance, for he not only gives facts showing that frost does not affect the tires, but he states the real cause of such accidents as are generally attributed to the frost.

He states:—"It has been asserted in evidence given at the coroner's inquest on the Hatfield accident, that the breaking of the steel tire was occasioned by the intensity of the frost, which is supposed to render the metal brittle, and of which this particular tire was composed. This is the opinion of most persons, but judging from my own experience such is not the fact, and provided we are to depend on actual experiment, it would appear that temperature has little or nothing to do with it. Some years since I endeavoured to settle this question by a long and careful series of experiments on wrought-iron, from which it was proved that the resistance to a tensile chain was as great at the temperature of zero as it was at 60° or upwards, until it attained a scarcely visible red heat. To show that this was the case, and taking, for example, the experiments at 60°, it will be found that the mean breaking weight, in tons, per square inch, was in the ratio of 19·930 to 21·879, or as 1 : 1·098 in favour of the specimens broken at the temperature of zero. The generally received opinion is, however, against these facts, and it is roundly asserted that the strength of iron and steel is greatly reduced in strength at a temperature below freezing. The contrary was proved to be the case in wrought-iron plates, and assuming that steel follows the same law, it appears evident that we must look for some other cause than change of temperature for the late fracture of the tire on the wheel of the break-van of the Great Northern Railway. . . . The immense number of purposes to which both iron and steel are applied, and the changes of temperature to which they are exposed, renders the inquiry not only interesting in a scientific point of view, but absolutely necessary to a knowledge of their security under the various influences of those changes; and when it is known that most of our metal constructions are exposed to a range of temperatures varying from the extreme cold of winter to the intense heat of summer, it is assuredly desirable to ascertain the effects produced by those causes on material from which we derive so many benefits, and on the security of which the safety of the public frequently depends. It was for these reasons that the experiments in question were undertaken, and the summary of results are sufficiently conclusive to show that changes of temperature are not always the cause of failure, as that which occurred near Hatfield on the Great Northern Railway. That such is the fact, I may adduce several accidents of broken tires all of which occurred during the spring and summer months when the temperature was high. One of them occurred on the Lancashire and Yorkshire Railway in the summer of last year when the temperature was 50° to 60° above freezing. I could enumerate others in which the winter frosts had nothing to do with the fractures which ensued."

After referring to some other experiments, Sir W. Fairbairn proceeded: "The danger arising from broken tires does not, according to my opinion, arise so much from changes of temperature *as from the practice of heating them to a dull red heat, and shrinking them on to the rim of the wheels.* This, I believe, is the general practice, and the unequal, and in some cases, the severe strains to which they are subject, has a direct tendency to break the tires. To show how easily this may be effected, let us suppose that a tire, two feet six inches or three feet diameter, is shrunk on to a wheel one-tenth of an inch larger than the tire, it then follows that the tire in cooling must be elongated to that extent, with a strain equivalent to the force of the shrinkage, and calculated to produce that amount of molecular disturbance. It may be more or it may be less, but supposing the strain to be one-half or three-fourths of that which would break the tire, it then follows that the constant action of its irregular motion on the rails must ultimately lead to fracture.* I am not surprised that this should be the case, as most, if not the whole, of railway tires, excepting those on engines and tenders, are not turned, but selected by hand, heated and shrunk upon the wheels with every degree of tension, as suits the convenience of the workman. So long as this process is pursued the public will be exposed to the risk of broken tires. What is required in this description of manufacture is, that the rim of the wheel and the inside of the tire should be *turned to a standard gauge*, accurately calculated to give the required amount of tightness with a larger margin of strength, and this done we should attain greatly increased security to the public, and a great saving in wear and tear—to say nothing of the large sums expended by companies in the shape of compensation for injuries and loss of life."

Here, then, is another potential triumph for more scientific accuracy and more hope for travellers.

* From long-continued action under strain, it has been proved that it is only a question of time when rupture takes place, as repeated increased and diminished changes with the same load ultimately leads to fracture.

SCIENTIFIC SERIALS

Poggendorff's Annalen der Physik und Chemie, 1870, *No.* 9.—The contents of this number are:—(1.) "Calorimetric Researches," by R. Bunsen. In the first part of this paper Prof. Bunsen describes the construction and method of using a new calorimeter, in which quantities of heat are measured by the amount of ice at 0° which they are capable of converting into water at the same temperature. The quantity of ice melted is in its turn indicated by the resulting diminution of volume, as shown by the movement of a mercury-column in a graduated capillary tube communicating with the vessel in which the ice is contained. In order to convert the results obtained by this method into absolute heat-units, it is necessary, either that the motion of the mercury-column produced by a known quantity of heat should be ascertained, or that the specific gravity of ice at 0° and its latent heat of fusion should be known. The first of these quantities was found by observing the effect produced by a given weight of boiling water, and the second by a process which may be described as consisting in the application of the principle of the weight-thermometer to measure the change of volume which water undergoes on freezing. From these data the third of the quantities mentioned, or the latent heat of fusion of ice, is readily calculated. Of the numerical results, given in the paper, we will quote only the following:—

Specific gravity of ice at 0° C	0·91674
Latent heat of fusion of ice	80·025
Specific heat of indium	0·0570
Specific heat of calcium	0·1704

One special advantage of this method of calorimetry is that it allows good results to be obtained with very small quantities of material; for instance, for specific heat determinations, from 0·3 gramme to, at the most, 4 grammes is sufficient. (2.) "On the relations between the crystalline form and chemical constitution of some organic compounds," by P. Groth. (3.) "Experimental and theoretical investigation of the figures of Equilibrium of a liquid mass without weight" (Eighth series), by J. Plateau. A translation of this paper, which relates to the conditions of the ready production and of the persistency of liquid films, to the superficial tension of liquids, and to their superficial viscosity, was printed in the *Philosophical Magazine* vol. xxxviii. p. 445 [1869.] (4.) "On the Absorption of Light," by Paul Glan. Among other results, the author finds that the absorbing power of a substance, when it is employed in solutions of different degrees of concentration, increases in a greater ratio than the concentration; also, that the absorbing power of a body in solution is affected by the nature of the medium in which it is dissolved. The experimental results are followed by a mathematical discussion of the mechanism of the absorption of light. (5.) "Additional researches into the behaviour of Vapours in relation to the Laws of Mariotte and Gay-Lussac," by Dr. Hermann Herwig. This paper has reference to an earlier one published in vol. cxxxvii. of *Poggendorff's Annalen.* The author finds that, when the pressure upon a vapour at a given temperature is diminished so far that the vapour obeys Mariotte's law, that is to say, so far that the product of the pressure into the corresponding volume becomes constant, this product bears to the similar product, when the pressure is great enough to cause the vapour to be saturated at the same temperature, a constant ratio which is proportional to the square root of the absolute temperature. In the present paper it is shown that ethylic bromide and carbonic sulphide conform to this law. (6.) "Some analogous Theorems in Photometry and in the Laws of Attraction," by Wilhelm von Bezold. The mathematical law of the inverse square of the distance applying equally to the illumination produced by a luminous point, and to the force exerted by an attracting particle, it follows that the mathematical expressions by which photometrical relations are expressed, will also admit of an interpretation in relation to the action of attracting particles. In this paper the double interpretation of the same formula is pointed out in several important cases. For example:—The author shows that the photometrical analogue of an equipotential surface drawn about several attracting particles, is a surface so placed, relatively to luminous points, whose luminosity is proportional to the masses of the particles, that the illumination of each element of the surface is greater than that of any other element passing through the same point. (7.) "On the Luminosity of Phosphorus," by W. Müller. The author finds that phosphorus vapour is not luminous in the absence of free oxygen; that it is not luminous at ordinary atmospheric temperatures when in contact with pure oxygen of atmospheric pressure, but that it becomes luminous, and at the same time absorbs oxygen, when the pressure is diminished to a certain amount, depending on the temperature, the necessary reduction of pressure being greater when the temperature is lower; and that phosphorus which has been for some time in contact with certain vapours, (notably hydrocarbons), is deprived by them of the property of becoming luminous on the admission of air, although air, mixed with the same vapours, is not thereby deprived of the power of exciting (temporary) luminosity in phosphorus. (8.) "On the Superoxides that can be prepared by Electrolysis," by W. Wernicke. (9.) "On a mechanical theorem applicable to Heat," by R. Clausius. (10) "On the Spectra of negative Electrodes, and of long-used Geissler's Tubes," by Prof. Edm. Reitlinger and Prof. Moriz Kuhn. (11.) "On the Meissner Lignite modified by contact with Basalt," by Dr. A. von Lasaulx. (12.) "On the analysis of Silicates," by E. Ludwig. Refers chiefly to the precautions required for the accurate separation of silica and alumina. (13.) "On the absorption-spectrum of liquid peroxide of Nitrogen," by August Kundt. On comparing the absorption-spectra of liquid and gaseous peroxide of nitrogen, the author found that the ill-defined black bands in the spectrum of the former coincided in position with strongly-marked groups of lines in the spectrum of the latter. (14.) "On the work done by Gases in Motion, or remarks on the paper so entitled," by Dr. A. Kurz. This is a reply to a criticism by Dr. Boltzman (noticed in NATURE, vol. ii. p. 364) of a previous paper by the author.

SOCIETIES AND ACADEMIES

LONDON

Zoological Society, January 17.—Prof. Newton, F.R.S., V.P., in the chair. The Secretary read a report on the additions to the Society's menagerie during the month of December 1870, amongst which were particularly noticed a specimen of the Two-toed Amphiuma (*Amphiuma didactylum*), and an example of Erxleben's Monkey (*Cercopithecus Erxlebeni*). On concluding his report the Secretary called attention to the registers of accessions to and deaths in the Society's menagerie, which lay on the table, and showed, in contradiction to statements recently published by Dr. Gray, that they were faithfully kept up, and that a revised abstract of the former was published every year as an appendix to the Society's "Proceedings."—Mr. Howard Saunders exhibited and made remarks on a series of skins of eagles belonging to *Aquila imperialis*, *A. bifasciata*, and *A. nævioides*.—A letter from Mr. R. Brown was read, recommending the introduction of hogs into countries where poisonous serpents were frequent, in reference to a communication from the Governor of Santa Lucia, read at the last meeting of the Society.—Mr. Jules Verreaux made some remarks on the facility with which the colouring matter in the wings of the Touracous was soluble, and stated that he had observed it washed out in the living birds by heavy rain.—Mr. J. E. Harting exhibited and made remarks on a specimen of Sabine's Snipe, recently killed in Ireland.—Mr. Sclater made some remarks on the amphibians usually called Axolotls, now living in the Society's gardens, and pointed out that if what Prof. Baird had recently stated were correct, these were not the true Axolotl of the lakes of Mexico (*Siredon mexicanum*), but the larval form of a known Salamander—*Amblystoma mavortium*, Baird. Mr. Sclater likewise exhibited a typical specimen of *Ateles variegatus*, Wagner, and pointed out its unquestionable identity with *A. Bartletti*, Gray.—Mr. J. W. Clark read a paper on a fine skull of the Narwhal (*Monodon monoceros*) with two tusks in the Cambridge University Museum, to which were added full particulars as to all the known bidentate skulls of this animal.—A paper was read by Dr. J. C. Cox, C.M.Z.S., containing descriptions of some new species of Australian land-shells.—Prof. Newton exhibited and made remarks on some new and rare birds' eggs, amongst which were those of the Sanderling (*Calidris arenaria*) and Lesser Sheath-bill (*Chionis minor*).—Mr. St. George Mivart pointed out the characters of a new genus of Insectivorous Mammals proposed to be called *Hemicentetes*, founded on the *Erinaceus madagascariensis* of Shaw, to which was added a revised synopsis of the known genera of the order Insectivora.—A communication was read from Mr. A. G. Butler, containing descriptions of some new species of Exotic Lepidoptera.—Mr. G. F. Angas communicatad a list of additional species of marine mollusca to be included in the Fauna of Port Jackson and the adjacent coasts of New South Wales.—Mr. Sclater read some notes on the typical specimens of *Tyrannula mexicana*, Kaup, and *T. barbirostris*, Swainson.—A second communication from Mr. Sclater contained remarks on certain species of *Dendrocolaptidæ*, in the collection of the Smithsonian Institution.

Geological Society of London, January 11.—Joseph Prestwich, F.R.S., President, in the chair. The following communications were read:—1. "On the older Metamorphic Rocks and Granite of Banffshire," by T. F. Jamieson, F.G.S. The author indicated three divisions in the metamorphic strata a Banffshire:—At bottom of great thickness of arenaceous beds, more or less altered into quartz-rock, gneiss, and mica-schist; next a series of fine-grained clay-slates, in the midst of which is a bed of limestone; and then again an upper group of arenaceous strata. The author stated that the arrangement of the rocks is very similar to that occurring in Bute and Argyleshire. He remarked that the general texture of the beds is fine-grained, and considered that they were probably deposited in the depths of the sea, off the mouth of a great river, the deposition of the argillaceous strata having taken place during a period of increased depression. The deposition of the beds was said to have probably taken place after the formation of the (Cambrian) Red Sandstone and Conglomerate of the North-west Highlands, or in Lower Silurian times, the river by which the sediment was brought down being supposed to have drained the great Laurentian region to the north-west. After their accumulation the author supposed that "a glow of heat from beneath" approached them, causing expansion and the wrinkling of the mass into folds running from S.W. to N.E. The granites were considered by the author to owe their origin to the fusion and recrystallisation of the arenaceous beds. Prof. Ramsay observed that the general section wonderfully corresponded with that given many years ago by Sir Roderick Murchison, of the Silurian and Laurentian rocks at Cape Wrath, and it seemed to him that the large views originally propounded by Sir Roderick were confirmed by the author. He was glad that the metamorphic origin of granite was supported by Mr. Jamieson, as he had held that view for several years, and he was pleased to find that opinions which had formerly met with so many opponents were constantly gaining acceptance. The fusion of these sedimentary rocks by metamorphic action was not identical with the fusion of lava, but their fluidity might be the same; and if that were the case there could be no difficulty in accepting the possibility of the injection of such fused rocks into crevices and fissures. The crumpling of the beds, however, was due to more extensive causes than those contemplated by the author. The proportion of igneous rock injected into contorted rocks, like those of North Wales, was almost infinitesimal, and the crumpling could hardly be due to mere local causes.—Prof. Ansted referred to what he had observed in the north-west part of Corsica, where about 40ft. of granite were distinctly interstratified between perfectly unmetamorphosed beds of sandstone and limestone, without any alteration at the points of contact, such as would be produced by an igneous rock. He also cited the crumpled strata in the Maritime Alps, in which the granites were parallel with the other beds, and seemed to form part of them. Mr. Carruthers mentioned that the late Prof. Fleming twenty years ago had taught the same doctrine as to the nature of granite as that held by the last speakers.—Mr. David Forbes agreed that the crumpling of the strata was not due to the intrusion of any eruptive rock. He completely disagreed with Prof. Ramsay and the author as to the origin of granite, and maintained that, in the sedimentary rocks traversed by the granite, the requisite ingredients for the formation of granite did not exist. The proportion of felspar in quartzose rocks was infinitesimally small, as compared with that entering into the composition of granite. He could not accept the notion of the heat from the interior approaching gradually to some portion of the surface. Prof. Ramsay, in reply to Mr. Forbes, maintained that some of the slaty rocks of Wales, by extreme metamorphism, would pass into some kinds of granite. As to the conditions of metamorphism of the rocks, this process must have gone on at a time when these older rocks were overlain by a great thickness of more recent beds which have since been removed by denudation. 2. "On the connection of Volcanic action with changes of Level," by Joseph John Murphy, F.G.S. The author commenced by discussing the chemical theory of volcanic action, which he considered he had disproved. He remarked on the coincidence of volcanic action with elevation of the surface, but stated his opinion that the elevation of one part of the earth's surface and the depression of another, are the results of a movement of subsidence in the following manner:—The interior of the earth is constantly cooling, and as it cools it must contract. But the cold strata of the surface cannot contract in the same proportion; and as they must remain in contact with the core, they are compelled to form folds and ridges. The breaking out of volcanoes is due to the breaking of part of the earth's crust by these foldings. According to the author, "volcanic action is not the cause, but the effect of secular changes of level; and secular changes of level are due to the subsidence of the surface on the interior, as the interior contracts in cooling." 3. "On some points in the Geology of the neighbourhood of Malaga," by Don M. de Orueba. Communicated by Sir R. I. Murchison, F.R.S., F.G.S. After referring to the writings of previous authors upon the geology of the south of Spain, the author noticed a mountain-chain near Antequera, one branch of which, known as the "Torcal," he described as presenting a very singular appearance from the huge blocks of stone of which it is composed. The division of the rock into separate blocks, often of the most fantastic shapes, was attributed by the author to denudation by water. The "Torcal" consists of a compact limestone, generally of a red colour, resting conformably on the east upon a fine-grained white oolitic marble of considerable thickness. At the divisional line between the two formations many Ammonites were said to occur, and three of these were doubtfully identified with *A. giganteus*, *biplex*, and *annulatus*. These species would indicate the deposit to be probably of Portlandian age. The plain of Antequera was considered by the author to consist of Tertiary formations. One of these, at the south of the city, he regarded as analogous to the

"Calcaire grossier." He mentioned indications of the presence in the vicinity of a Miliolitic marble, and of a limestone containing Nummulites. Between Antequera and the Torcal, he noticed a small calcareous deposit containing many forms of *Gryphæa*. The paper was illustrated by photographs of two scenes on the Torcal, and of several species of Ammonites. Prof. Ansted remarked that the condition of the Torcal was similar to that prevailing in many other limestone districts, and was probably due to subaerial denudation. Mr. W. W. Smyth mentioned that he had lately had an opportunity of examining, at Cadiz, a collection of fossils formed by Mr. Macpherson in that district, which also contained specimens of Ammonites. It appeared that there were large tracts in which the rocks appeared almost destitute of fossils, which rendered their classification extremely difficult; and great credit was due to the author for his exertions in a country where unfortunately so little interest was taken in geology. He mentioned that some of these unfossiliferous rocks had been classified as Silurian by some French geologists; but for this there was not the slightest evidence. It appeared far more probable that they were of Jurassic age. Some red beds, which had been called Triassic, were also in all probability Tertiary. Mr. Gwyn Jeffreys, who had examined several collections in Spain and Portugal, stated that he had been much struck with the absence of newer Tertiary fossils, the latest being of Miocene age. These latter presented a tropical aspect, and differed from the mollusca now inhabiting the neighbouring seas. Mr. Blake was not satisfied with the determination of the Ammonites, which appeared to him rather of Cretaceous than Jurassic forms. Mr. Tate observed that the French geologists had determined the existence in Spain of the whole Jurassic series, from the Lower Lias to the Portlandian beds; and, judging from the photographs, he should consider the Ammonites to be Jurassic. Mr. Boyd Dawkins cited the remains of *Rhinoceros etruscus*, procured by the late Dr. Falconer at Malaga, as affording evidence of the presence of Pliocene age in that district. Prof. Duncan mentioned that he had found corals of the genus *Flabellum*, such as were found in the Tejares clays, in recent deep-sea dredgings in the Atlantic, and among specimens brought from Japan.

Linnean Society, January 19.—Mr. G. Bentham, president, in the chair. "Historical Notes on the Radix Galangæ of Pharmacy," by D. Hanbury, F.R.S. The introductionof this drug into Europe appears to have been due to the Arabians; its common use in the West does not date earlier than the 15th century. It is an aromatic stimulant, and may be used to replace ginger; but the high virtues ascribed to it by the ancients cannot be sustained.—"On the Vegetation of the Solomon Islands," by Mr. J. Atkin. The writer had spent some months in these little-known islands, chiefly in Christoval, the southernmost of the group, which lies between 10° and 11° S. lat., and between 162° and 163° E. long. The whole group extends for about 300 miles eastwards to Papua, over $4\frac{1}{2}°$ of longitude and 4° of latitude. They are mainly of volcanic origin; the low lands consist of coral, which reaches to an elevation of from 300 to 500 feet. Earthquakes are very frequent, almost every month, but not very severe. The nearest active volcano is Tinkalu, 200 miles to the westward. The wet season is in winter, especially the early part of July, when an enormous quantity of rain falls. The temperature is remarkably uniform; the writer had never seen the thermometer below 75° F. or above 88° in the shade, or 132° in the sun; the air is extremely damp. The highest land in Christoval is from 3,000 to 4,000 feet elevation, and is probably granite. The island is entirely covered with vegetation, except near the sea. Grasses are very few. In the forests are very few trees with trunks five feet in diameter. The bush is very thick, and climbers numerous. One Aroid was noticed, and eight or nine Orchids, all epiphytal. Several Zingibers, including the true ginger, native. Three or four species of Pandanus, which are extremely variable. The cocoa-nut and sago palms are native, the latter growing eighty feet high; also the areca-palm, and the betel-nut; the latter is universally chewed. The yam is grown, as well as five other roots probably belonging to the same order. The bread-fruit is abundant; and a variety of mango grows wild, as well as a bitter orange. The leaf of the sago-palm is used for thatch. There is a Cycas thirty or forty feet high, which is sometimes branched. Of ferns the genera most observed were Asplenium and Acrostichum; but no tree-ferns, although they are so abundant in the neighbouring Banks's group. Two Convolvuli were noticed and an Ipomœa; two Hibisci, two Casuarinæ, and two Acacias, a tree and a shrub; also a Begonia, the same species as in Banks's group; and a handsome species of nettle. The men are short, with dark curly hair. They use spears, and sometimes bows and arrows; their canoes are very beautifully ornamented. Animals are comparatively few. Dogs and pigs are abundant, both apparently native; also opossums and a small rat. There are many beautiful birds; the white cockatoo is never seen, though so abundant in islands separated by a channel only fifteen miles broad. Insects are plentiful. Snakes, both land and water, abound, but none are poisonous. Scorpions are numerous but small. Alligators were found, but not abundant. Frogs plentiful; lizards innumerable; one iguana was seen four feet long.—"Note on *Byrsanthus*," by Dr. M. T. Masters, F.R.S. The chief interest of this paper lay in the author's exposition of the relation between the glands and the perfect stamens.

SPECTROSCOPIC OBSERVATIONS OF THE AMERICAN ECLIPSE PARTY IN SPAIN

THE complete and accurate account of the observations of the American Eclipse party in Spain, under the charge of Prof. Winlock, which was given by Prof. Langley in NATURE two weeks ago, renders any further report of our spectroscopic work almost unnecessary; and yet perhaps a somewhat fuller statement with reference to one or two points may not be wholly superfluous.

Of the four spectroscopes employed, two were what might be called *analysing*, and two *integrating* instruments. The analysing instruments are designed to study separately the spectrum of different portions of the prominences and corona, only a small part of the object being examined at a time; the integrating instruments, on the other hand, deal with the entire mass of light received from the whole luminous body, without distinction of parts. In the first class of instruments, a distinct image of the object is thrown upon the slit by the object-glass of a large telescope, each point in the slit receiving light from only one point in the object. In the second class no image is thrown upon the slit, every point of which receives light from every point in the object; and if a telescope is used at all (as was the case with Mr. Pye's instrument), it must have a field of view large enough to include the whole object, and must have its eye-piece adjusted for distinct vision of a star—*i.e.*, in such a manner that the rays from a star shall be parallel when they leave the eye-piece. In this case the telescope increases the angular diameter and area of the object, and consequently the amount of light received, without otherwise at all changing the conditions.

Prof. Winlock's instrument and my own were of the former class. Prof. Winlock had a spectroscope of two prisms attached to an equatorial of $5\frac{1}{2}$in. aperture, and about 7ft. focus. My own instrument had (during the totality) the dispersive power of seven prisms, and was attached to an equatorial of $6\frac{4}{10}$in. aperture, and $8\frac{1}{2}$ft. focal length.

The instruments of Messrs. Abbay and Pye were of the integrating kind. Mr. Abbay's had the collimator and observing telescope and two of the prisms which belonged to my old five-prism instrument. It was provided with the means of comparing the observed spectrum directly with the spectra of hydrogen, sodium, magnesium, and iron.

Mr. Pye's instrument was much smaller, but as its prism was made of the extra-dense flint, its dispersive power was very nearly the same as Mr. Abbay's; and the addition of a small telescope in front of the slit, magnifying about $2\frac{1}{2}$ times, and thus increasing its light about six-fold, made it, I think, fully the equal of the other in power and efficiency.

Professor Langley has so well stated what we saw, that it is not necessary to repeat it; but I cannot refrain from putting on record that the sudden reversal into brightness and colour of the countless dark lines of the spectrum at the commencement of totality, and their gradual dying out, was the most exquisitely beautiful phenomenon possible to conceive, and it seems to me to have considerable theoretical importance. Secchi's *continuous spectrum* at the sun's limb is probably the same thing modified by atmospheric glare; anywhere but in the clear sky of Italy so much modified indeed as to be wholly masked.

I wish at this time to call special attention to the evidence which we obtain as to the extent of the self-luminous corona, or "leucosphere," as it has been recently named,* by combining the indications of the two classes of instruments.

By my direction Mr. Pye recorded the brightness of the lines which he saw during totality on an arbitrary scale from 10 down. These are his numbers, C 8·5, D_3 5·5, 1474 10, F 3. I suppose the actual amount of light of each kind would be roughly proportional to the squares of these numbers, for we seem instinctively to call one luminous object twice or thrice as bright as another when it would give the same light at twice or thrice the distance.

If so, the numbers representing the relative amounts of light would stand C 72, D_3 30, 1474 100, and F 9, neglecting fractions.

Now, in the analysing spectroscope the case is very different, and it is difficult to make an accurate estimate; but I think those who have been accustomed to observe both C and 1474, would admit that their ratio of brightness is something the same as that between a first and fifth magnitude star; *i.e.*, C is at least 25 times and perhaps 50 times as bright as 1474. Even during the totality, 1474 can hardly be called conspicuous in an analysing instrument, while C blazes like a red Sirius. It seems necessary, therefore, to assume that the area which emits the 1474 light is to the area which gives C, roughly in the proportion of 100×25 (or 50) to 72—that is to say, the angular area of the self-luminous corona is from 35 to 70 times as great as that of the red stratum of hydrogen and prominences combined. I suppose these taken together would be about equivalent to a ring 15″ high surrounding the sun, and this would make the self-luminous corona equivalent to another ring from 8′ to 16′ high.

Of course I am aware that the numerical data of this calculation are very uncertain, and I have therefore neglected all considerations of shading and inequality of illumination. But the principle is, I think, correct, and it has this advantage. The presence of a light cloud or haze does not sensibly affect the result, because the calculation is based solely on the ratios between lights of two different kinds in the two different instruments, and these ratios would not be seriously affected unless the cloud absorbed one kind of light more than the other.

With the analysing spectroscope alone the case is entirely different; a light cloud or haze vitiates everything. Thus some of the observers, favoured with a less clear sky than we at Xeres, saw the C and F lines even on the moon, undoubtedly by reflection from thin clouds. I saw myself the C line as far as 6′ or 7′ from the sun, far above any possible hydrogen atmosphere.

Therefore, although Prof. Winlock and myself both saw the 1474 line to a distance of more than 16′ from the sun, I should not dare to lay much stress on that observation as showing the true limits of the self-luminous coronal matter. I base my belief that the limit of 15′ or 20′ is reached by it in

* This name seems inadmissible, except as one of the sub divisions of the chromosphere.—ED.

some of its angular prolongations, more upon the observations of 1869, when the sky was exceptionally clear, than upon anything seen at this time; and yet all the observations of this year, so far as I can see, accord well enough with the idea.

The two faint lines which I saw last year between D and 1474, and which I thought might also be corona lines, were not seen this year by any one, so far as I can learn. I certainly saw two such lines last year, but I was not then at all positive about their belonging to the corona (I have felt somewhat annoyed by finding them put on the same footing as 1474 in several publications of the last year or two), and my present impression is that they were two of the faint iron lines that often appear in protuberances in that portion of the spectrum.

The question has been raised whether the corona line *exactly* coincides with the 1474 dark line in the solar spectrum. The difference, if any (and I have not found the slightest reason to suspect the least want of coincidence in observations with the whole dispersive power of 13 prisms), is less than $\frac{1}{10}$ of one division of Kirchhoff's scale.

Just before the totality began, I placed the slit of my spectroscope exactly tangential to the sun's limb at the point which would be last covered, and brought the 1474 line, already bright, as is usually the case at the base of the chromosphere, exactly to the cross hairs. After the totality had fairly begun, I moved the equatorial in right ascension until the slit was more than 16′ east of the sun's limb, and the line remained continually visible, though of course growing fainter as the distance from the sun increased. There is not the slightest possibility of mistake, nor of error beyond the limit named, *i.e.*, $\frac{1}{10}$ of one division of Kirchhoff's scale.

And now a few words in relation to the nature of the Corona. It seems to me to be a complex phenomenon, made up of at least four, perhaps five different elements; and in the main I concur with the views put forth by Mr. Lockyer in a recent number of NATURE, with the exception that I should be disposed to assign a greater relative importance to the truly solar portion of the phenomenon than he appears to do.

1st. We have, I think, surrounding the sun, beyond any further reasonable doubt, a mass of self-luminous gaseous matter, whose spectrum is characterised by the green 1474 line. The precise extent of this it is hardly yet possible to consider as determined, but it must be many times the thickness of the red hydrogen portion of the chromosphere: perhaps, on an average, 8′ or 10′, with occasional horns of twice that height. It is not at all unlikely that it may even turn out to have *no upper limit*, but to extend from the sun indefinitely into space.

2nd. This region undoubtedly reflects to us a certain amount of the ordinary photospheric sunlight. This reflected light is of course polarised radially to a considerable extent. Its spectrum ought to show the ordinary dark lines, but they are partly masked in the manner Mr. Lockyer has so happily explained, and partly by the faintness of the spectrum.

3rd. Our own atmosphere, even when clearest, must apparently extend this corona, both outwards, and inwards upon the moon's disc. Since, however, the inner edge of the coronal ring is far the brightest, the inward extension of the corona should be most marked, except at the very beginning or end of totality, and I have no doubt it is: that is to say, at the middle of totality the illumination of the moon's disc gives a somewhat exaggerated measure of the effect of our own atmosphere in extending the corona outwards. Accordingly, I am disposed to think the effect of the atmosphere (when clear) is a very subordinate one, since in 1869 the light upon the moon's disc was only very trifling compared with that even a whole degree from the sun. This atmospheric light would also be polarised radially. Its spectrum would be mainly that of the chromosphere, prominences, and "leucosphere" combined, a discontinuous bright line spectrum.

4th. There must be a large subjective element, for two even skilled observers, standing side by side, describe phenomena differing in very essential points.

5th. I am somewhat inclined to think with Oudemans (see his paper published in NATURE Nov. 10) that possibly *cosmical dust* between us and the moon may play an important part. Assuming a light cloud of such matter, one or two hundred thousand miles above the earth's surface and of great thickness, it becomes easy to account for the straight dark streaks, the varying form (if it does vary), and many other puzzling phenomena of the corona-phenomena which can hardly be produced by portions of our own atmosphere deeply immersed in the lunar shadow, but which, I own, seem to me now less aurora-like and less certainly solar than they did a year ago. I do not see how optical tests by polariscope and spectroscope could discriminate between the effects of such a cloud and those of our own atmosphere.

C. A. YOUNG

POPULAR NAMES OF BRITISH PLANTS

The Popular Names of British Plants. By R. C. A. Prior, M.D., F.L.S. Second Edition. (Williams and Norgate.)

THERE are many botanists who know little of the English names of Plants; and there are many who know these intimately, yet are not botanists. Both classes will welcome this comprehensive volume: and those who possess neither a philosophical nor a popular knowledge of the subject, will yet find abundant interest in a book, which is the work of an accurate scholar and philologist, as well as of a scientific botanist.

Most interesting, and perhaps least expected, is the light which these names throw upon the history of early civilisation. Many of them date from a period antecedent to the European settlement of the Aryan race, and enlighten us as to the habits of our remote ancestors some thousand years ago. We discover from them that the men who continuously advanced through many countries, from the confines of India to the British Islands, were no race of savages, but a comparatively civilised community: that they understood letters; that they had a knowledge of the useful metals; that they possessed the principal domestic animals; that they cultivated the oak, the beech, the birch, the hawthorn, the apple; grew wheat, barley, oats, rye, beans; built timber houses and thatched them; hedged their fields and fenced their gardens.

In a later class of names, which betray the intercourse of our forefathers with Roman cultivation and Grecian poetry, many a strange piece of myth or history lies embalmed. Thus the *Centaury* is the plant with which the Centaur Chiron healed the wound received from the poisoned arrow of Hercules. The beautiful and rare wild *Pæony* recalls Pæon, the physician-god of Homer, who healed the bellowing Ares when smarting from the spear of Diomed. The *Juno's Rose*, or tall white lily, preserves a story curiously transformed in later times from the Pagan to the Roman Catholic Mythology. The *Treacle-mustard* (Erysimum cheiranthoides) is the "Theriacum,' invented as an antidote by the Emperor Nero's physician, and reappearing long afterwards as an ingredient in the Orvietan, or Venice Treacle. Mediæval tales and legends in abundance find illustration from the same source. The *Carline Thistle* is the herb which miraculously healed a pestilence that attacked the army of Karl the Great. The sea-loving *Samphire* is corrupted from Saint Pierre, the fisherman Apostle. The *Flower-de-Luce*, or Iris, was the device of Louis VII. The *Filbert* commemorates the horticultural skill of king Phillibert. The *Herb Robert* cures a disease named after Duke Robert of Normandy, The *Margarette*, or Daisy, owes its name to St. Margaret of Cortona, known to the readers of Mrs. Jameson.

More than one curious superstition is embalmed in well-known names. The *Celandine* is an altered form of the Greek "Chelidon," a swallow, because with its yellow juice the swallows were supposed to restore sight to their blinded young ones. The *Hawk-weed* records a like belief respecting the Hawk. The *Fumitory* (fume-terre) was thought to be produced without seed by vapours rising from the earth.

Many names, as *Wound-wort*, *Tetter-wort*, *Pile-wort*, *Nipple-wort*, have survived the ancient faith in their medical efficacy. And here comes in the strange principle of nomenclature, known as the "Doctrine of Signatures." Where the external appearance of a plant resembled any disease, or any part of the human body liable to a disease, such resemblance was taken as an indication of its especial healing virtue. The spotted leaves of the *Lung-wort* must be a specific, it was thought, for tubercular disease of the lungs; the scaly pappus of *Scabious* for cutaneous eruptions; the hard stony seeds of the *Gromwell* for stone in the bladder; the throat-like corolla of the *Throat-wort*, or Canterbury bell, for sore throats; the knotty tubers of *Scrophularia* for scrophulous glands. The pretty *Toad-flax* of our walls and hedges owes its name to a strange mistake. Believed in early times to be a cure for a complaint known as "Buboes," it received the Latin name of "Bubonium." A confusion between Bubo and "Bufo," Latin for a Toad, gave birth to its present name; and stories were not long wanting that sick or wounded Toads had been seen to eat of it and to recover health.

Similar distortions occur in names not medically expressive. *Apricot*, connected ordinarily with the adjective "Apricus," sunny, is a corruption through the Spanish and Italian of "Præcoqua," early; having been looked upon as an early peach. *Sweet William* is transformed from "Æillet," a little eye; *Pink* is shortened from the Low German "Pinksten," Whitsuntide, a name due to the season of its blossoming. *Gilliflower* comes through *Giroflée* from "Caryophyllus," a clove. *Carnation* is from "Coronation," its flowers being used in chaplets. *Marigold* is Marsh-gold; *Cowslip* is "Hose-flap," applied originally to the large flannelly leaf of the Mullein; *Dame's Violet* from "Damascene" Violet; the blunder being kept up, as is often the case, in the Latin "Hesperis matronalis." *Hip* is the same word with *Jujube; Hawthorn* is "Hedge-thorn;" *London Pride* is named not from the smoky metropolis in which it thrives, but from a Mr. London, who introduced it. *Snap-dragon* is "Snout-dragon." *Daffodil*, more properly *Daffadowndilly*, is a combination of "Sapharoun" or "Saffron-lily" with "Asphodelus," the old English "Affodilly." With the taste for alliteration often shown in popular names, the Sapharoun-lily, blending with Affodilly, became by a mutual compromise Daffadowndilly, whence Daffodilly and Daffodil. *Peach* (Persicus), *Damson* (Damascenus), *Shalot* (Ascalonicus), and *Spinach* (Hispanicus), retain in their names dim memories of the lands of their birth. But the most curious instance of blundering is the *Jerusalem Artichoke*. It is a sun-flower, not an artichoke; but its tubers resemble the artichoke in flavour. From its Italian name "Girasole," turn-to-the-sun, came "Jerusalem;" and by a further quibble the soup which is made from it is called "Palestine soup."

Of the miscellaneous names many are equally interesting. The *Laburnum*, closing its petals at night like a tired labourer; the *Campion*, which crowned the champion of the tournament; the *Lady's Bedstraw*, recalling the days when mattresses were not, and when this fragrant Galium was used for ladies' couches; the *Heartsease*, with its many amorous synonyms; the *Shamrock*, concerning whose botanical identity no two Irishmen can agree; the *Lavender*, or Washerwoman, scenting freshly washed linen; the *Ozier*, from the oozy beds in which it grows, are a few out of countless specimens. The philologist may delight to trace the root of *Apple* from the Zend and Sanscrit "Ap" to the Latin "Pa" in "Padus," "Po" in "Pomum" and "Poto." Those familiar with Hans Andersen will read with fresh enjoyment the tale of the "Wild Swan," when they learn that the *Nettles*, which the Princess had to weave into shirts, are derived from the verb "ne," to spin or sew. On the other hand, some pretty time-honoured traditions are ruthlessly swept away. The *Narcissus* is referred, not to the enamoured Grecian youth, but to the Sanscrit "Nark" or Hell; and the protesting lover of the classics is reminded "that Proserpine was gathering Narcissi long before Narcissus was born." The *Fox-glove*, is not, as we had loved to think, like the *Troll-flower* and *Pixie-stool*, the "Folks'" or Fairies' "Glove"; but the Foxes' *Glew*, or Tintinnabulum, with its ring of bells, hung on an arched support. Worst of all, the charming story of the Forget-me-not, current in every European language, is a later legend framed to meet a name already extant. For the original use of the name, its first curious transference of allusion, its final attachment to a river-side flower, and the narrative of the drowning lover, which readily grew up to adorn it, we must refer our readers to Dr. Prior's book. They will be surprised to find a treatise on Botany poetical, and a Dictionary light reading. They will learn how much a technical subject may be enlivened by varied accomplishments in him who treats it; they will see that in the Science of Botany, as in every other Science, the widest culture brings about the most telling and effective teaching.

W. TUCKWELL

OUR BOOK SHELF

A Ride through the disturbed Districts of New Zealand, together with some Account of the South Sea Islands. Being Selections from the Journals and Letters of Lieut. the Hon Herbert Meade, R.N., edited by his Brother. With Maps and Illustrations from the Author's Sketches. (Murray, 1870.)

THE title-page sufficiently describes this book, which is illustrated by some nice woodcuts, and several coloured lithographs of less merit. There is a good description of the Geysers of New Zealand, and of the state of the native insurrection in 1865; with some exciting narratives of attacks on Papuan cannibals in the New Hebrides. A good-sized house, built in a lofty tree and used as a fort, was seen in one of the Solomon Islands. One cannot but regret that the opportunities possessed by our officers on the Pacific Station for investigating the little-known natural history of the islands, are so seldom utilised. The author of this book often shoots, but hardly seems aware that his game could be of any other use than for food. The only natural history passage in the book is the following, dated Upolu, Samoan Islands :—" Saw a very rare bird, the Dodunculus, native name, which is peculiar to this island. It has the feet of a pigeon, beak of a hawk," &c., &c. Dodunculus ! native name ! ! A. R. W.

Metals, their Properties and Treatment By C. L. Bloxam, Professor of Chemistry in King's College, London ; Professor of Chemistry in the Royal Military Academy, and in the Department of Artillery Studies, Woolwich. Pp. 296. (London : Longmans, Green and Co., 1870.)

THIS is one of the text-books of science which are being edited by Mr. T. M. Goodeve and published by Messrs. Longmans. The series is intended to supply a want that has long been felt of exact and complete works on mechanical and physical science for the use of schools, and for the self-instruction of working men. A difficulty must have been experienced by many who are engaged in teaching science, when asked to recommend a small and inexpensive text-book, which may at the same time be so simply and clearly written as to be useful to those who have not had a scientific education, and who have not the advantage of being able to attend long courses of lectures. Many popular books on scientific subjects have been written, but they are not unfrequently somewhat inaccurate ; difficult questions being often omitted, or, what is worse, treated in a superficial manner which is likely to mislead the student, inducing him to believe that these questions are very simple, and deluding him with the notion that he knows all about them. He is thus frequently disappointed at a subsequent period by finding that on studying the subject more minutely, it is much more complex than he at first imagined, and that many of the simple ideas which he had carefully fixed in his mind have to be discarded, and new ones acquired.

The book opens with an introductory section on the properties and treatment of metals, containing many useful tables, such as specific gravities, fusing points, conductivity, &c. The more common metals used in the arts are alone discussed, so as not to introduce unnecessary complication. The remaining sections of the book treat of iron and steel, copper, tin, zinc, lead, silver, gold, mercury, platinum, palladium, antimony, bismuth, aluminium, magnesium, and cadmium. The last six being far less important than the others, are very shortly described, and only occupy twelve pages.

Each section commences with a description of the ores of the metal under consideration, their composition being given, and also the per-centage of metal present. This is followed by the methods of treating the ores in order to extract the metal, chemical reactions being written in words without formulæ, so hat no preliminary knowledge is necessary. The mechanical treatment of the reduced metal is then detailed, and its useful applications in the pure condition or in the form of alloys. The book is profusely illustrated with good woodcuts, and is written in an extremely interesting manner which cannot fail to attract the attention of the student. This, together with the trustworthiness of its contents and its low price, will render the treatise extremely useful for scientific instruction. If the remaining text-books of the series possess all the advantages which are presented by this one, the thanks of teachers and students of science will be due to the editor and publishers for their undertaking.

Odd Showers: or, Explanations of the Rain of Insects, Fishes, and Lizards; Soot, Sand, and Ashes; Red Rain and Snow; Meteoric Stones; and other Bodies. By Carribber. (London : Kerby and Son, 1870.)

THIS little book is stated on the title-page to be " intended chiefly for young persons;" but others will, doubtless, gain information from it, as to the causes of the sudden appearance of swarms of insects and other animals, and showers of rain tinged with various colours, with respect to which so many popular errors are afloat. The writer derives his experience from a long residence in Canada, and one explanation of so-called "showers of blood" is new to us, that it is caused by the exudation of a crimson fluid by various chrysalides when passing into the imago state. The writer states that, on one occasion, twenty-eight chrysalides of *Vanessa antiopa*, the Camberwell Beauty, which he had preserved in a small room, underwent transformation in a single day in July ; when the walls and floor were bespattered with a bright crimson-coloured substance resembling blood, as to give the appearance of a regular shower of the fluid.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Natural Science at Cambridge

IN NATURE for January 12, 1871 (p. 209), there appeared an article headed "Natural Science at Cambridge," which has the air of having been promulgated *permissu* (if not *auctoritate*) *superiorum*. It is extremely gratifying to read the list of exhibitions and scholarships founded or proposed to be founded in certain Colleges in this University, but the concluding sentence of the article has struck me as having been penned by one with whom the wish was father to the thought. It is said that "most of the Colleges are understood to be willing to award Fellowships for merit in Natural Science equivalent to that for which they are in the habit of giving them for Classics and Mathematics." Now this is entirely at variance with my own opinion on the subject, formed on a somewhat wide acquaintance with members of various colleges ; and I would beg of the writer to be good enough to inform the public through your columns, first, how many Fellowships have solely and actually been awarded for merit in Natural Science, and, secondly, which of the sixteen colleges, besides Trinity, have absolutely declared that a Fellowship shall be the reward of great proficiency in Natural Science. I need not say how glad I shall be to find that my opinion is erroneous. M. A.

Cambridge, Jan. 28

Yellow

IT was not from any experiments of my own, but on the authority of Helmholtz, that I asserted the identity of brown with a dark yellow or orange. He found that the pure red and yellow of the spectrum gave the various shades of brown when seen by the side of more brilliantly lighted white surfaces. (Physiologische Optik, p. 281.) There is therefore nothing in the nature of the colour to exclude complete saturation, although it may well happen that most of the browns we ordinarily see fall somewhat short of it.

In NATURE of Jan. 26, Mr. Munro calls attention to the great brilliancy and saturation of many natural yellows as accounting for the difficulty of resolving them into their components. It is, no doubt, quite true that a full yellow could not be compounded of such reds and greens as we come across in daily life, but it is equally certain that a drab or dilute yellow could be; and yet no one recognises the fact by his unaided senses, or thinks it anything but strange and unlikely when told of it. And after all, can it properly be said that natural yellows are more saturated than other colours? That they approach more nearly the corresponding tints in the spectrum is admitted; but is that test a fair one? It seems to me that the homogeneous yellow itself must be considered as dilute when brought into comparison with the nearly primary red and green.

I have another difficulty in accepting Mr. Munro's explanation. A suitable mixture of any red, green, or blue will give a neutral grey. All four come within our every-day experience; but such a result seemed to Goethe, soon after Newton proved it, a paradox of paradoxes, and I believe to unsophisticated minds it seems so still.

Mr. Munro has ingeniously shown from the colour equations that there is no more primary blue in my blue disc than about $2\frac{1}{2}$ as much as in the red *plus* $1\frac{1}{3}$ as much as in the green—a conclusion which seems somewhat startling. In choosing the coloured papers and cards for the discs, I had great difficulty in finding a green that was even tolerably good, and the one that I finally used reflected large quantities of blue light. I had some thought of trying a green silk disc, which was of a much better colour, but feared errors depending on the different character of the surface.

It is not hard to see a reason for the comparative scarcity of good greens. To obtain a good red orange or yellow by means of absorption, all that is necessary is to cut away the spectrum above a certain point; for a good blue, the rays standing below a given one in refrangibility must be got rid of; but in order to isolate a green in anything like purity, the absorbing agent must hit off *two* points of the spectrum, removing all below one point and all above the other. The result is, that while nearly saturated yellows and reds abound—the scarlet of the geranium is almost perfect—hardly a good green is to be met with. The best I know is a mixture, prepared by adding bichromate of potash to a strong solution of sulphate of copper. The addition of a little chloride of chromium to remove the yellow more effectually is perhaps an improvement. If Mr. Munro would care to see the colours which I used for the discs, I should be very happy to send him samples.

Terling Place, Witham, Jan. 29 J. W. STRUTT

Comets' Tails

MAY there not be a connection between the colour of the sky and the tails of comets?

Suppose a comet to be surrounded with a wide-spread transparent atmosphere, holding in suspension matter as finely divided and as invisible as the sky-matter of our earth; and suppose the more condensed, but still transparent nucleus to act as a lens, throwing a beam of light upon the otherwise invisible mist of that atmosphere, could not most of the phenomena of those puzzling tails be thus accounted for?

Leicester, Jan. 28 FREDERICK T. MOTT

Ocean Currents

MR. LAUGHTON's letter in the latest number of NATURE shows that the suggestion of a probable influence of differences of atmospheric pressure on ocean currents has not been stated with sufficient clearness.

That a hydrostatic equilibrium would exist under a permanently unequal distribution of the pressures over the ocean, as Mr. Laughton argues, is not to be doubted. But is there any such permanent arrangement?

Granting that the high-pressure area of the trade-winds is nearly constant, varying little from day to day, and only expanding and contracting its limits gradually in summer and winter, the pressures to northward of this over the Atlantic are by no means so steady. Though they give on the average of the year, or even of the month, a *lower* pressure, yet the daily observations show that the pressures over wide areas may vary considerably, rising at one time to equal that of the Trade-wind patch, at another falling very much below it. Quoting from the daily barometric curves registered in the Quarterly Report of the Meteorological Office (for April—June, 1869), "On the 13th of May in that year, the seven stations whose weather is there recorded (Valencia, Armagh, Glasgow, Aberdeen, Falmouth, Stonyhurst, and Kew) show simultaneously a barometric pressure of 30·1 inches." On the 6th of May these stations had severally reported a pressure of only 28·9 inches. A difference of pressure equal to that of 16 inches of water had taken place over the entire extent of the British Isles, and probably over a much greater space.

The system of synchronous observation is not yet sufficiently extended to enable any positive statement of the general direction of the movement of low pressure areas across the North Atlantic to be made; but there is a strong probability that such depressions travel in a direction continuing the path taken by the hurricanes of the West Indies, since the majority of barometric hollows reach the British Isles from west or south-west. Just as the waters are forced to rise into the central low pressure of a hurricane (to the extent of several feet) and to follow its path, so, in a less degree, does it seem probable that the movement of extended and less violent depressions may influence the ocean currents.

The rate of progress of such depressions appears to be in an inverse ratio to their extent and depth. A West Indian hurricane moves onward at a rate of only fifteen miles an hour (Buchan's Meteorology, p. 269), and the highest speed of European storms, according to the same authority, is forty-five miles an hour; but that minor depressions may travel with much greater velocity is shown by reference to the quarterly report before noticed, where is the record of a hollow of from three to four tenths of an inch, which passed over the British Isles on the 24th of February, 1869, at the rate of ninety miles an hour.*

Either in causing a considerable change in the level, or in rapidly moving over it, from near an area of constantly high pressure, through a region where the average pressure diminishes, such depressions must surely influence the surface of the ocean, and either aid or retard its currents. That a difference in level of four inches in 1,800 miles can scarcely under any circumstances give rise to a current of twenty miles a day (the word hour in Mr. Laughton's letter is probably a typographical error) is also clear, but the temporary difference in level may be much greater than this within a much shorter distance. The average rate of the north equatorial current, moreover, in the Trade-wind region, is shown by the pilot charts of the Admiralty to be only from ten to twelve miles a day, and it is only claimed for difference of atmospheric pressure that it has some small share in aiding the formation of the current in question.

KEITH JOHNSTON, JUN.

Insulation of St. Michael's Mount, Cornwall—When did it occur?

THIS is a very interesting question, and the reader will be enabled to judge for himself, presently, whether there are not sufficient historical facts on record to enable us to answer—"In the eleventh century."

Domesday Book, date 1086, in the part relating to "Cornvalge" (*i.e.* Cornwall), at p. 2, has the following, which I have translated from the abbreviated Latin—"*The Land of St. Michael.*—Keiwal holds the church of St. Michael. Brismar was holding it in the reign of King Edward. There are two hides which never paid the Danish tax [nunquam geldaverunt]. The land is 8 carucates. There is 1 carucate with 1 villan, and two bordarii, and 10 acres of pasture. Value 20 shillings. Of these 2 hides, Earl Moriton took away 1 hide, value 20 shillings." And accordingly, at p. 11 of Domesday Book, there appear in the descriptive list of the many estates of Earl Moriton, corresponding particulars of the 1 hide which he had taken away.

Now, in the first place, Domesday Book gives no reason whatever for believing that, at its date, St. Michael's Mount was an *Island*, neither does Magna Britannia, vol. 1, p. 303, where the Mount is called *Mychel-stop*, or Michael's place. And in every case, while "annoting" those holding possessions in "Cornvalge," there is an entire absence in Domesday Book of any mention of island or islands on any of the coasts of Cornwall, just as if there had been then no islands on those coasts of sufficient extent to be worthy of mention. On the other hand, it is the

* The Meteorological Report shows that in January, 1869, 12 depressions reached the British Isles from W.-ward; in February 10, also from W.; in March 8 (5 from W.); in April 7 (5 from W.); in May 8 (7 from W.); and in June 2 from W.

custom in Domesday Book *when any place is an island, to call it so.* For example, in vol. i., folio 75, "Dorsete" [Dorset], we have—"The land of the King. The King holds the island which is called Porland [*i.e.* Portland]. King Edward held it in his life." And again, same vol., fol. 396—"Hanteschire [*i.e.* Hampshire]. These lands below written lie in the isle of Wit" [*i.e.* Wight].

In short, the Mount could not have been an island in 1086, because it then contained at least eight times as much land as it does at present, probably connecting it with the mainland, from which it is even now only one-third mile distant. The truth, Sir Henry Ellis says, seems to be that a hide, a yardland, a knight's fee, &c., contained no certain number of acres, but varied in different places at different times. He says there are "four virgates in each hide, and thirty acres to make a virgate." The elementary acre was 40 perches by 4 perches, as now. And, accordingly, the 8 carucates would amount to the respective numbers of acres mentioned in the last column of the following table at the respective times:—

Periods	Acres in a Carucate	No. of Carucates	Total Acres
Carucate temp. Richard I.	60	8	480
do. do.	100	8	800
do. Edward I.	180	8	1440
do. 32 Edward III. (Oxon)	112	8	896
do. Middleton	150	8	1200

The hide is generally supposed to have been 120 acres. Now, taking the smallest of these measures, we shall have for the two hides 240 acres. The present area of the Mount, however, is only 30 acres, so that there are 210 acres missing. How can we account for them except by supposing that the Mount extended further, perhaps in every direction? The hide of land taken by Earl Moriton was given to Mont S. Michel,* on the French coast where Normandy joins Britanny, in 1085.

I have before me "Two of the Saxon Chronicles parallel," edited and commented on by the Rev. John Earle, formerly Professor of Anglo-Saxon, Oxford, from which the two following remarkable passages are extracted for the respective years 1014 and 1099.

"1,014. And on this year, on Saint Michael's-Mass-Even, came that great sea-flood through widely this land, and ran so far up as never before not did, and submerged many towns, and mankind innumerable number," p. 151.

"1,099. This year also, on St. Martin-Mass-Day, sprang up that exceeding sea-flood, and so much to harm did, as no man not remembered that it ever afore did, and was that same day a new moon," p. 235.

Nobody seems to contend that the coasts of Cornwall have simply been abraded and cut back by the action of the sea during the Christian period. Nor does anyone appear to doubt that there has been a *subsidence.* Now there are 210 acres of land missing since 1086, and in 1099, thirteen years *after*, we have a record of a catastrophe which would fully account for the loss! Supposing, whilst travelling in a foreign country, we were to come suddenly upon a city in ruins, when we had personally experienced shocks of earthquake a short time before. How could we doubt that the earthquake was the cause of the ruins, and how can we doubt that the remarkable event of 1099 caused the loss of land by subsidence and the Insulation of the Mount?

Sir Henry de la Beche (Report on Cornwall, &c., p. 417, *et seq.*) says "submarine forests are so common that it is difficult not to find traces of them in the district at the mouths of all the numerous valleys which open upon the sea, and are in any manner silted up." . . . . It is well known that abundance of roots and stumps of trees have been found *in situ* for some distance on the south of the Mount. And no one seems to doubt that "the Mount was formerly five or six miles from the sea, and enclosed with a very thick wood," and that it was called in the Cornish language "the hoar rock in the wood."

I have before me the very interesting Prize Essay by Mr. John E. Thomas, F.G.S., written for the National Eisteddfod, held at Chester, 1866, upon the "Encroachment of the Sea between the River Mersey and the Bristol Channel." † Prof. Ramsay, who had the adjudication of the prize, says, "The result is so good, that I think this part of the Essay well worthy of the prize of 10*l.* and a medal." Mr. Thomas does not look further back than the year 520 for his sinkings in Cardigan Bay (p. 13). A perusal of the whole tract of twenty-four pages will well repay gentlemen who take an interest in this particular department of geology.

Measurement of Mass

PROF. EVERETT's first letter contains the statement "Deschanel, in accordance with what has been till recent years an almost universal custom, employs a variable unit of force, and as depending upon this, a variable unit of mass, so that the number denoting the mass of one and the same body is diminished as the body is carried from the equator to the poles, and would increase up to infinity if the body fell to the centre of the earth."

I wished to point out that in making the standard pound a unit of force, by defining the place where it is to be used, we do not adopt a unit of mass which is variable, since if we take three times as much matter as gravitates with the unit force, we shall obtain the same mass at whatever point of the earth's surface the comparison is made. I cannot see that the adoption of this method necessitates any filing or loading of weights to suit change of latitude, since we invariably employ an ordinary balance and not a spring balance to effect our weighings.

Whenever it does become necessary to compare gravitating forces, we are obliged to fall back upon the use of the pendulum, whether we adopt the old system of standards or the new.

As a philosophical theory I am perfectly ready to admit that the standard pound is most appropriately considered as a standard of mass, but the employment of this standard in a text-book for the use of beginners seems calculated to lead to confusion.

If we refuse to commit ourselves to the absurdity of comparing the quantity of one kind of matter with the quantity of another kind of matter, I hardly see how *mass* is to be defined except by means of weight, and without, for the moment at least, employing weights as measures of force.

The assumption of a hypothetical force of gravity not dependent on latitude seems to stand on the same footing as the employment of a *mean solar day*; it is convenient, leads to no confusion, and is not unphilosophical. W. M. W.

Mount Etna

IT may interest the observers who have lately been in Sicily to hear that since their departure there has been a sad falling off in the appearance of Etna. The grand wreath of steam that used to roll out of the crater at such stately leisure that you could hardly detect any movement without close attention, suddenly ceased about three days ago, and left nothing more than a tiny wisp of smoke, rather suggestive of a cottage chimney than a volcano. I call it smoke because the colour became decidedly darker than it used to be, and the manner of its dissipation is different. Formerly, after issuing from the crater it used to assume true cloud forms, and lie about the mountain exactly like clouds: now, it diffuses itself as a thin veil over the sky; sometimes being traceable in a streak as far as the coast of Calabria. Its volume is perhaps a thousandth part of what it was last week. It issues in a distinctly spiral form, the wreath oscillating apparently from side to side of the crater; and sometimes there are little puffs of extra size, whilst at others the wreath is nearly sundered.

The date of the change cannot be very precisely given, although I have watched the mountain at all hours of the day for a week past, in hopes of getting a correct outline of it for pictorial purposes. The clouds only cleared off completely yesterday; but I observed that a change in the wreath had taken place as early as Friday the 13th January. The weather up to the 15th has been outrageously squally and rainy, but is now superb. Last night there was a magnificent display of zodiacal light, considerably brighter than we saw it at Augusta before the Eclipse, and distinctly traceable up to the zenith; the apex of the cone reaching to within about 10° of the Pleiades. It was brightest about 7 P.M., but was still visible at 10 P.M., when clouds shut it out.

Taormina, Sicily, Jan. 17 JOHN BRETT

Note on Chromosphere Lines

A VERY small but very bright prominence on the N.W. limb of the sun, observed at Xeres Dec. 21st, gave in addition to the ordinary protuberance bright lines the following—one below C at 656 Kirchhoff's scale precisely corresponding to an iron line in the solar spectrum—also 3 at 1601, 1605, and 1607, the reversal of a well-known group of *Chromium* lines. The latter I believe are new in prominence spectra.

C. A. YOUNG

Eozoön Canadense

I HAVE just observed that in your number for December 22 a correspondent revives some of the old but often refuted objections to the organic nature of Eozoön. As the mail closes in a few hours, and I have lectures in those hours, I cannot reply by this opportunity; but shall crave a small share of your space next week to show that the objections stated are unfounded; and to state what is now being done here in further illustration of this ancient and veritable fossil. J. W. DAWSON

M'Gill College, Montreal, Jan. 16

THE battle for the *Eozoön Canadense* may be left to Messrs. Carpenter, Jones, King, Rowney, and other eminent microscopists, but perhaps an outsider may be pardoned if he asks some anomalies to be explained.

In the Ophytes of Bennabeola the mountain group in Connemara, or rather Yar-Connaught, Mr. Sandford proved the existence of the *Eozoön Canadense*, and his opinion was backed up by Mr. R. Jones and also, if I remember rightly, by Dr. Carpenter. There are acres upon acres of limestone in that country of the same age, and some of them on the same geological horizon as the Ophytes, Ophicalcytes, Ophimagnesytes and Ophidolomytes; yet, in no plaec, except where Ophyte or one of its varieties exist, has the Eozoönal structure been found. Furthermore, when the West Galway Ophytes are followed in depth they graduate into a Schistose-dolomyte that may be micaceous, felsitic, or quartzitic, and contains more or less calcyte; yet in these dolomytes there is no trace of the Eozoonal structure.

These rocks of Yar-Connaught are said to be of Lower Silurian (Cambro-Silurian) age, by Sir R. I. Murchison, Prof. Harkness, and other eminent geologists. In other parts of the world will be found square miles upon square miles of rocks, of the same geological age, often having inliers of limestones, yet in them there is no *Eozoön Canadense*, it only being found in a peculiar rock (pseudomorph-dolomyte) in this small tract of Lower Silurian rocks, in Yar-Connaught.

Yar-Connaught, Jan. 23 G. H. KINAHAN

IF my previous letter, as alleged by Dr. Carpenter, exhibits a complete misapprehension of the state of our knowledge of the above fossil, I cannot plead in extenuation a want of familiarity with the arguments he again brings forward in support of the organic theory. Had he, instead of explaining away imaginary difficulties, addressed himself to those that really exist, his reply would have possessed greater value. Let us examine how my objections have been met.

Firstly, then, Dr. Carpenter cannot affirm that any specimen of Eozoön has been obtained from unaltered rocks. He can go no further than to say that his best specimens are from rocks that have undergone the *least* metamorphic change. Thus it appears after all, that it is only a question of *degree* in metamorphism; and when we consider that Logan, Dawson, Sterry Hunt, and himself, in their original papers, constantly alluded to these Eozoönal rocks as crystalline, highly crystalline, of serpentine marble, &c., we are enabled to judge of the value of the diminutives "little" and "least," now used when it becomes necessary to the argument to soften down these expressions. Sir W. Logan, who is an authority on the subject, says: *—"Any organic remains which may have been entombed in these limestones would, if they retained their calcareous character, be almost certainly obliterated by crystallisation, and it would only be by the replacement of the original carbonate of lime by a different mineral substance, or by an infiltration of such a substance into all the pores and spaces in and about the fossil, that its form would be preserved." It would be strange indeed if, during the millions of years since the deposition of the Laurentian limestones, they had undergone no change, and notwithstanding Sterry Hunt's depositional views, the consensus of opinion is in favour of serpentine itself being a product of alteration.

* "Geological Journal," No. 81, p. 48.

Had Dr. Carpenter pointed out where serpentine pyroxene or loganite had been found in unaltered rocks, instead of dwelling upon the internal casts of foraminifera distinguishing the Greensand formation, his remarks would have been more relevant to the subject. These casts, it is well known, are in glauconite, a hydrous silicate of protoxide of iron and potash. Whether or not the silicates replacing the sarcode bodies of the foraminifera dredged up by Capt. Spratt in the Ægean, are the result of precipitation from sea water, caused by the decomposition of the sarcodic substance, is quite immaterial to the argument; but if, as is assumed, the chambers of Eozoön were filled in the same manner with serpentine, and this chemical reaction was necessary to its precipitation, how are we to account for the serpentine investing huge blocks of pyroxene, and the solid bands of the same mineral intercalated in the limestone? If, therefore, I admit the possible infiltration of certain silicates into the *body* of Eozoön—did such an animal ever exist—it is no help to those who favour the organic hypothesis. I have, however, neither affirmed nor denied such a possibility, as it is entirely outside of my line of argument.

As regards *hydrothermal* action, which it appears is objected to if called in to aid my theories, I may say it is a matter of indifference what the *agency* be so long as the *alteration* is proved.

It would take up too much of your space for me to go into the details of the "canal system," "nummuline layer," "chamber casts," "Stolon passages," "pseudopodial tubules;" and such is unnecessary, as Profs. King and Rowney have pretty well exhausted the subject, and, to my mind, have conclusively proved the existence of identical forms of purely mineral origin. If, as is alleged, the canal system always crosses the cleavage planes, and is never between them, such would appear to be correlative mineral phenomena, and tells against the organic hypothesis. I object, however, to a question of such wide bearing being settled solely on the authority of Dr. Carpenter as a microscopist. If others are wrong, let him demonstrate the fact, which his great experience will more readily enable him to accomplish.

If I have misconstrued the following passage into an admission which he now repudiates, I am ready to make ample apology; perhaps, however, he will explain to what the term "elsewhere" refers. After combating the notion that the *nummuline* layer can be precisely parallel in a purely mineral production, he says he is "prepared to maintain the organic origin of Eozoön on the broad basis of cumulative evidence afforded by the combination in every single mass of an assemblage of features which can only be *separately* paralleled elsewhere."*

Such is Dr. Carpenter's unbounded faith in Eozoön—though every hypothesis attempting to bring it into the category of organic beings is beset with difficulties—that he would not be surprised to find it existing now in the deep-sea bottom. There is, he says, no *a priori* improbability in such an event happening, and indeed there is not, for the persistence of types is one of the most remarkable of zoological facts. But as the area in which Eozoön is to be found is enlarged, and the duration of its time lengthened, our difficulties increase. If the infilling material of the chamber casts is due to substitution during decomposition, or to direct deposition as suggested by Sterry Hunt, there is no possible reason why we should not find Eozoön in some of the immense masses of unaltered limestone which still exist. I repeat that it has never yet been found in such rocks, but always in those that have been metamorphosed. If again serpentine is not a product of alteration, why do we not find it in unaltered rocks? The inference is obvious, they are correlative phenomena, and therefore Dr. Carpenter must pardon me if I decline at present to adopt his views. Still I am open to conviction, and will freely admit my error when, after some of his deep-sea dredgings, he brings home the modern Eozoön fossilised with a silicate, and when, in addition, it is discovered in an unaltered limestone fossilised with serpentine pyroxene or loganite.

The Eclipse Expedition

HOW about the Eclipse Expedition, which, I presume, you helped to sanction? I informed the public that it would prove a complete swindle, and so it has turned out. As long as such professional liars as the Astronomical Society are allowed to gull the nation, what chance is there of arriving at the truth?

JOHN HAMPDEN

Scientific Nomenclature

THE Kakapo or Night Kaka of New Zealand, *Strigops habroptilus*, described in NATURE at p. 190 as the *ground* parrot, is called the owl-parrot by Mr. Wood in the current number of the "Student." So long as both names are given there is no confusion, but it is otherwise if a full description is omitted; and I have to suggest that it is very desirable to adopt a uniform usage upon all occasions.

It is curious to notice the analogy between the words *psittakos* of ancient Greece and the *Kaka* of aboriginal New Zealand; as the Greek word has been traced to a Sanscrit origin it would seem that the New Zealand word must have originated since the Aryan descent upon India. A. H.

NATURAL SCIENCE AT CAMBRIDGE

THE following Lectures in Natural Sciences will be delivered at Trinity, St. John's and Sidney Sussex Colleges during the Lent Term, 1871. On Electricity (for the Natural Sciences Tripos,) by Mr. Trotter, Trinity College, in lecture room No. 11, on Tuesdays, Thursdays, Saturdays, at 10, commencing February 4. On Electricity and Magnetism (for the special examination for the B.A. degree), by Mr. Trotter, Trinity College, in lecture room No. 11, on Mondays, Wednesdays, Fridays, at 10, commencing Wednesday, February 1. On Chemistry, by Mr. Main, St. John's College, on Tuesdays, Thursdays, Saturdays, at 12, in St. John's College, Laboratory, commencing Tuesday, January 31. Instruction in Practical Chemistry will also be given. On Geology, by Mr. Bonney, St. John's College: (1) Palæontology, on Wednesdays and Fridays, at 9, commencing Wednesday, February 1; (2) Lyell's Principles of Geology, on Tuesdays and Thursdays, at 9, commencing Tuesday, January 31; (3) Elementary Lectures on Tuesdays and Thursdays at 11, commencing Tuesday, January 31. On Structural and Morphological Botany, by Mr. Hicks Sidney College, in the College Laboratory, on Mondays, Wednesdays, Fridays, at 10, commencing Wednesday, February 1. On Physiology, by the Trinity Prælector of Physiology (Dr. M. Foster), at the New Museums, on Wednesdays, Thursdays, Fridays, at 11, beginning Wednesday, February 1. The Physiological Laboratory will be open for pratical instruction in Physiology daily.

It may be remembered that a year ago we pointed out some defects in the prospectus issued for the intercollegiate teaching of Natural Science by Trinity and St. John's Colleges, Cambridge. We are glad to find that, as will be found from the above statement, these have been rectified, and that by the appointment by Trinity College of Dr. Michael Foster as Prælector of Physiology, and by combining with Sidney College, and so availing themselves of the services of Mr. Hicks of that College, who obtained the first place in the Natural Sciences Tripos, as lecturer on Structural and Morphological Botany, the staff has been greatly strengthened, and the prospect of thorough teaching proportionately increased. The lectures are open to members of the other colleges upon payment of a small fee.

OCEANIC VERTEBRATES*

SO far as concerns their distribution, animals may be divided into two classes, the tenants of the land and fresh waters, and the inhabitants of the ocean. In the one case their boundaries depend upon the form and extent of continents past and present; on the other, upon the corresponding limits of the ocean.

Little enough is as yet known with certainty about the general distribution of terrestrial animals; about those of the ocean we are still more ignorant. It is, therefore, with great pleasure that we have received Prof. Giglioli's notes on the vertebrated animals which were met with during the voyage of the Italian frigate *Magenta* round the world. The scientific command of this expedition was originally entrusted to Prof. Philippi of Turin. Upon his lamented death at Hong Kong, the author of the present treatise, we believe, succeeded to the post, and is now busily engaged in working out the results obtained by the expedition in every branch of natural history. The present memoir, although founded on observations made during the voyage of the *Magenta*. seems to be only incidentally connected therewith, and to have been prepared with reference to a competition for the Chair of Zoology and Comparative Anatomy at the Royal Institute of Practical Studies in Florence.

Professor Giglioli commences his remarks by treating of the oceanic fishes met with during his voyages. Although it is quite true, according to the popular idea, that the sea is full of fishes, it must be recollected that those that inhabit the mid-ocean are quite distinct from those that swarm round the coasts, and are not nearly so numerous. At the same time, many of them are remarkable for their brilliant colour, and are otherwise of special interest. It is difficult, says Professor Giglioli, to describe the beauty of the *Coryphæna hippuris* when first taken from the water: a thousand different tints of deep azure and golden yellow sparkle over its body, which, however, fade upon death with surprising celerity. Other oceanic fishes are the large *Thersytes*, various species of Tunny, the well-known Pilot fish (*Naucrates*), and the *Echeneis*, concerning which such marvellous tales are told by ancient writers. But, perhaps, the most attractive of all the group to the oceanic traveller are the flying fishes (*Exocetus*). Of this genus six species were met with during the voyage of the *Magenta*, each appearing to have a peculiar district of the ocean assigned to its range.

Of the class of reptiles which Professor Giglioli next speaks of, two orders only have oceanic representatives—namely, the Ophidia and Testudinata. Of the sea-snakes three species were met with belonging to the genera *Hydrophis* and *Pelamis*. This peculiar family of serpents was formerly supposed to be confined to the Indian Ocean; but it has of late years been discovered to extend its range over the Pacific, even up to the Gulf of Panama. Of the marine Turtles likewise three species, all well known, were observed.

The class of birds, which follows third in Prof. Giglioli's memoir, is much better represented on the so-called "desolate" ocean. Members of four large families of this class frequent the seas traversed by the *Magenta*, which were chiefly those belonging to the southern hemisphere. These are the Penguins (*Spheniscidæ*), the Petrels (*Procellariidæ*), the Gulls (*Laridæ*), and the Pelicans (*Pelicanidæ*). A fifth great oceanic family, the Awks (*Alcidæ*), replaces the penguins in the Arctic Seas, and was not met with by Prof. Giglioli. The most abundant of all oceanic birds are, of course, the petrels and albatrosses, of the family Procellariidæ, many of which pass by far the greater part of their lives in mid-ocean. Upwards of forty species of this group are enumerated as having been encountered during the circumnavigation of the *Magenta*, amongst which are several supposed to be new to science, and which are provided with new names accordingly.

The mammals of the ocean, which the present memoir lastly treats of, belong to three very different orders: the Cetaceans, Seals, and Sirenians. Of these the first alone pass their whole existence in the salt sea. All the marine Carnivores, so far as we know, habitually resort to land, or at all events to ice, which in polar regions serves the same purpose. and of the few existing members of the Sirenia, one at least is rather an inhabitant of fresh water than of salt. Prof. Giglioli's observations are chiefly confined to the Cetaceans, of which thirteen or fourteen

* Note intorno al'a distribuzione, della Fauna Vertebrata nell'oceano, presse durante un viaggio intorno al Globo, 1865—68, dal Professore Enrico Hillyer Giglioli. Firenze, 1870, 8vo. 96 pp.

species were met with in various parts of the ocean traversed by the *Magenta*.

At the end of his memoir, Professor Giglioli gives a kind of journal of his voyage, containing the approximate latitude and longitude of the *Magenta* upon each day of her circumnavigation, and the various species of vertebrates observed or obtained, in parallel columns. Further assistance in tracing the distribution of oceanic life is afforded by the concluding chart, in which the track of the vessel is exactly delineated, and the names of the principal animals met with on each spot are likewise given.

It will be thus seen that even an oceanic voyage round the world, without counting the foreign lands touched upon, affords ample opportunities for the student of nature who has the use of his hands and eyes. In sending a single frigate on such a voyage, the poverty-stricken government of Italy does not hesitate to put on board a band of scientific observers. Does Mr. Childers do the same, when he sends his flying squadron round the world composed of the largest and most expensive ships which wealthy England can produce? We are ashamed to say he does not. Any application, even, for a free passage for a naturalist on such an occasion, would receive the stereotyped refusal, and the answer that "my lords" had no funds to devote to such purposes, and no space to spare.

P. L. S.

EARTHQUAKES AT FIUME DURING THE YEAR 1870

THE following list of earthquakes at Fiume during the year 1870 is sent by a correspondent at that town, to whom it was furnished by Prof. E. Stahlberger, of the Naval Academy, together with an extract from the Journal of Meteorological Observation kept at that Institution, condensing the remarks, &c., of the original, and omitting such details as are of mere local interest, as well as descriptions of the apparatus used in marking direction. The year 1870 is not to be taken as a fair specimen of the frequency of earthquakes in this place. It was decidedly an exceptional year, both in this respect and with regard to the weather, which was unusually changeable throughout the whole twelve months, and during the autumn and December was marked by an abnormal amount of rain. About the time of the December full-moon a large halo of broad bands was noticed by our correspondent and others at about 8 P.M. On the 20th of May, at about 9 P.M., a very faint Aurora Borealis was visible.

No.	Day.	Time.	Duration.	Direction.	Remarks.
1	Feb. 23	0.22 P.M.	About 4 sec.	Apparently N.N.E. to S.S.W.	This beginning of the series of earthquakes came so unexpectedly that no apparatus was in readiness for marking the exact direction. The shock was violent; the oscillations succeeded each other with great rapidity.
2	Mar. 1	8.57 P.M.	5 sec	N.N.W. to S.S.E.	An alarmingly violent shock, the most violent that has occurred here for many years. Its commencement was sudden; it was accompanied by hollow, roaring sounds; the oscillations extremely rapid. Of all the shocks during the year, this was the most remarkable. It produced disastrous effects on the village of Clana, situate inland 2½ hours distant from Fiume. Out of the 150 houses there, 40 were rendered uninhabitable, and the rest were more or less injured. The walls mostly fell outwards, and no lives were lost.—(N.B. Not many walls fell, but very many were cracked the whole way down, and the houses left in so unsafe a condition that they were uninhabitable. I saw the village myself some time after the catastrophe, but before the repairs and rebuilding were made.—A. M. SMITH.)
3	Mar. 2	About 1 15 A.M.	....	N.W. to S.E. or N. to S.	Slighter as to violence.
4	Mar. 4	2.45 A.M.	5 sec.	N.W. to S.E.	Oscillations very rapid. On the preceding evening, at 7 5, a slight vibration of the earth was perceptible, lasting, with interruptions, two minutes. The same phenomenon was again observed at 11.14, about three hours therefore before the actual earthquake
5	April 28	3.25 A.M.	....	......	Two distinct shocks, separated by an interval of two or three seconds.
6	May 9	4.15 A.M.	....	......	Vibrations or tremblings were observed on April 29, at 7.30 A.M. and 2.28 P.M., and on May 4, at 2.30 A.M.
7	May 10	2 51 A.M.			
8	do.	9.19 A.M.			
9	do.	4 5 P.M			
10	do.	5 55 P.M.	....	Vertical	This was one of the more violent shocks, and was also felt at sea.
11	May 11	1.30 A.M.	....	N.W. to S.E.	Slight.
12	do.	2.15 A.M.	....	do.	do
13	do.*	2.50 A.M.	....	Vertical	Violent. It consisted of two distinct movements, separated by an interval of a few seconds, and was preceded by a thunder-like sound.
14	do.	4 15 A.M.	....	do.	Violent.
15	do.	4.30 A.M.	....	N.W. to S.E.	Slight.
16	do.	5 0 A.M.	....	do.	do.
17	do.	9 15 A.M.	....	do.	do.
18	do.	9 50 A.M.	....	do.	do.
19	do.	11 38 A.M.	....	do.	do.
20	do.	2 18 P.M.	....	do.	do.
21	do	During the night; time not specified	....	do.	do.
22	May 13	9 5 A.M.	....	......	do.
23	do.	11.19 P.M.	....	......	do.
24	May 14	0.50 A.M.	....	......	do.
25	May 16	10 (?) P.M.	....	......	A slight shock, preceded by a hollow groaning noise some short time previously.
26	do.	10 25 P.M.	....	......	Of short duration, but of some violence, consisting of two distinct shocks.
27	May 18	10.57 P.M.	....	......	Two slight shocks, following close on one another.
28	May 19	9.26 A.M.	....	......	Slight.
29	May 21	1.5 A.M.	....	......	Slight, preceded by a rolling noise of long duration, at 1.45 P.M. vibration,
30	May 23	8.25 P.M.	....	......	Slight.
31	do.	About 10.45 P.M.	....	......	do.
32	June 2	0 27 A.M.	3 sec.	......	Somewhat violent.
33	Sept 25	5'.43 A.M.	4 sec.	......	Slight, with loud thunder-noise.
34	Oct. 13	4 30 P.M.	....	......	Slight
35	Oct 17	8 0 P.M.	....	......	A double shock, with loud noise.
36	Dec. 16	1.50 A.M.	....	N.E.	Moderately violent.

* On this day, between 2.50 and 9.15 A.M., there were 27 insignificant movements not specified in the list.—A. M. S.

THE GENESIS OF SPECIES*

It is a remarkable illustration of the apparently fitful manner in which our knowledge of Nature increases, that the event which has probably been more fruitful than any other during the present century in inducing practical advances in the study of Natural History, was the promulgation of a pure theory, the publication, namely, by Mr. Darwin and Mr. Wallace, of the doctrine of the Origin of Species by means of Natural Selection. We say a pure theory, because the genesis of a new species is a phenomenon which never has yet, and probably never will, come consciously under the cognizance of man. We see forms of animal and vegetable life die out before our eyes, but their birth is not within our ken. As Mr. Darwin has pointed out, even should a new species suddenly arise, we have no means of recognising it as such. As a matter of fact, new plants and animals are constantly being discovered in all parts of the globe. Even in our own small and well-searched island, the additions within the last twenty years of more or less conspicuous flowering plants to our native flora are not inconsiderable; but no naturalist suggests any other interpretation of this, than that either they have been overlooked before, have been recently introduced from other countries, or that the seeds have been buried for ages in the soil. None the less, however, does it seem possible, or even probable, that we may eventually arrive at a correct solution of the problem by a rigorous induction from known facts.

So recently as the date of the publication of the first edition of the "Origin of Species," in 1859, Mr. Darwin wrote, "The great majority of naturalists believe that species are immutable productions, and have been separately created;" and the statement has been repeated in subsequent editions. We think, however, that it is impossible, at the present time, to sustain the correctness of this assertion. A writer in the "Botanische Zeitung"† has recently shown that there is some reason to believe that Linnæus himself, in later years, considerably modified the rigidity of his adherence to the doctrine which he laid down so decisively in his earlier writings:—"*Species tot numeramus quot diversæ formæ in principio sunt creatæ.*"‡ During the eighteenth and the first half of the present century, however, it was only a few naturalists of more than ordinarily keen powers of reasoning and prodigious knowledge of Nature—Lamarck, Buffon, Geoffroy St. Hilaire, Owen (in his earlier writings), and some others—who were bold enough to enunciate the theory that species have been created by a process of evolution from earlier closely-allied forms of life. Since the publication of the "Origin of Species," we may say that almost the whole body of the younger naturalists of this country and of Germany—Von Baer, Huxley, Spencer, and Haeckel leading the way after Darwin and Wallace—have given in their adhesion to the doctrine of Evolution. It is only within the last twelvemonth that the evolutionists can claim so great an accession to their strength as that distinguished systematist, the President of the Linnean Society.*

FIG. 1.—Leaf Butterfly in Flight and Repose.
The lowest apparent leaf on the stem is in reality the under side of the wing of the same butterfly which is represented in the upper part of the picture.

* "On the Genesis of Species." By St. George Mivart, F.R.S. (London: Macmillan and Co., 1871.)
† Botanische Zeitung, Sept. 9, 1870.
‡ Linn. Phil. Bot. Aphor. 157, p. 99.

* Bentham, "On the Species of Cassia," a paper read before the Linnean Society in 1870, but not yet published.

Along with this theory, these two writers introduced another, of the *modus operandi* by which this evolution is mainly or entirely effected, that of a process of Natural Selection from spontaneous variations. This doctrine was supported by an enormous array of facts, and by a brilliancy of argument which caused it at first to be as eagerly and generally adopted as the other. During the last few years, however, it may be said that a reaction has been setting in in an opposite direction, and attention has been widely called to difficulties in the way of the full adoption of the theory of Natural Selection, at first overlooked, the force of some of which has been admitted, with his usual candour, by Mr. Darwin himself. Some of these objections were pointed out by Mr. J. J. Murphy in

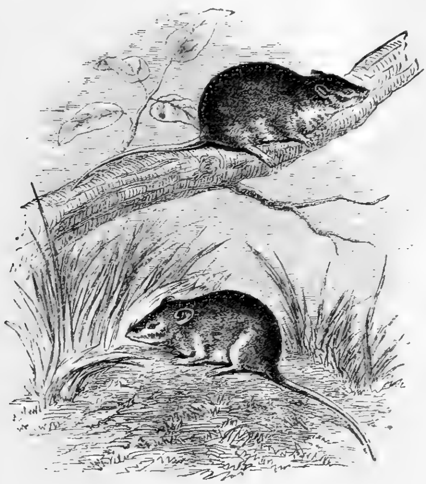

Fig. 2.—Upper Figure—Antechinus minutissimus (*implacental*).
Lower Figure—Mus delicatulus (*placental*).

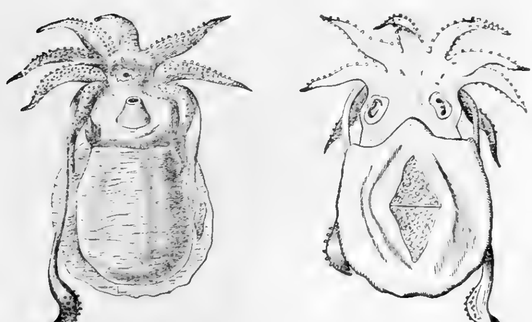

Fig. 3.—Cuttle-fish. Ventral and Dorsal Aspect.

his elaborate essays, entitled "Habit and Intelligence," published in 1869; on others Mr. Mivart dwells in the volume now before us, the most recent contribution to this department of literature.

A theory may be true, and yet may not be adequate. To take an illustration from the realm of mind. The believer in the doctrine of innate ideas will admit that the greater number of our conceptions are the result of habit, imitation, and training; he believes, however, that there are others which cannot thus be adequately accounted for, and which are innate and independent of subsequent education. In the same manner Mr. Mivart and those who think with him freely admit the potency of Natural Selection to have produced the greater number of the specific forms and organic structures we see around us; for the production of others they believe that it can be proved to be inadequate, and that we must look to some other innate principle for their formation. Mr. Mivart supports his arguments with so much cogency of reasoning, so great a knowledge of anatomical structure, and so complete an acknowledgment of the strength of his opponents' position, that they cannot be disregarded by any one interested in the subject. His objections are the more deserving of careful consideration, inasmuch as he states that he was himself by no means disposed originally to dissent from the theory of Natural Selection, if only its difficulties could be solved, but that he has found each successive year that deeper consideration and more careful examination have more and more brought home to him the inadequacy of Mr. Darwin's theory to account for the preservation and intensification of incipient specific and generic characters. It behoves, therefore, every Darwinian to satisfy himself that either Mr. Mivart's premisses or his line of argument is unsound.

The objections brought forward by the author are summed up as follows :—(1.) That Natural Selection is incompetent to account for the incipient stages of useful structures. (2.) That it does not harmonise with the co-existence of closely similar structures of diverse origin. (3.) That there are grounds for thinking that specific differences may be developed suddenly instead of gradually. (4.) That the opinion that species have definite though different limits to their variability is still tenable. (5.) That certain fossil transitional forms are absent which might have been expected to be present. (6.) That some facts of geological distribution supplement other difficulties. (7.) That the objection drawn from the physiological difference between "species" and "races" still exists unrefuted. (8.) That there are many remarkable phenomena in organic forms upon which Natural Selection throws no light whatever, but the explanations of which, if they could be attained, might throw light upon specific origination. If these objections are not new, they are at least sustained by new arguments. They are evidently of very unequal value. The third is very difficult of proof or disproof. The fifth may be true in our present state of knowledge, but would be very unsafe by itself as the basis of an argument. The first, second, and eighth are of greatest value, and are those which Mr. Mivart has most closely worked out.

Hitherto the attention of those scientific naturalists who have concerned themselves with the intricate problems of organic life, has been directed almost exclusively to the animal kingdom. This may have arisen from the greater attractiveness and practical interest of the study of zoology, or from the fact that in the popular mind (and we fear the error is not confined to mere "popular" writers) natural history and zoology are considered convertible terms. Be this as it may, the number of botanists, with the illustrious exception of Mr. Darwin himself, who look on their science in a philosophic spirit, is lamentably small. We believe, however, that more light will be found to be thrown on the problem of the genesis of species by a consideration of the phenomena of the vegetable than of the animal kingdom. Plants have less power of adapting themselves to new conditions, or of finding for themselves more congenial surroundings, than have animals. Their locality and their food are, as it were, prescribed for them by the circumstances of their birth; here, therefore, we might expect to find the rule of the survival of the fittest to reign supreme. We believe, however, it would be very difficult to substantiate any instances of species of plants being supplanted by other closely allied species, similar to those well-authenticated in the case of the rat and the cockroach. Plants when first artificially introduced into a new country undoubtedly frequently spread with extraordinary rapidity, to the destruction of weeds belonging to native races; but this is evidently not the mode in which species have supplanted one another in a state of pure nature.

Under Mr. Mivart's first head, he deals with the subject of Mimicry, contending that Natural Selection is incompetent to account either for the first or last stages of such wonderful instances of protective resemblance as that represented in our illustration. As this subject has been so recently discussed in these columns, we need not dwell upon it further than to remark, that we think the author could have supported his case with arguments of even greater force, had he extended his observations to the vegetable kingdom. The only object which it has been conjectured can be gained by a plant imitating a different species or a foreign structure, is to attract insects to assist in the distribution of its pollen. The most remarkable instances of the imitation by plants of foreign objects is in the case of the curious resemblance of the flowers of certain orchids to insects and other animals. One of the most singular of these is the well-known bee-orchis. But, as Mr. Mivart remarks, Mr. Darwin, in a course of observations extending over a series of years, has never seen a bee alight on this orchis. The most noteworthy resemblances again of plants *inter se* unconnected with organic affinity, are not in the flowers, where they might be useful, but in the leaves, or in the whole stem and foliage. It is difficult to conjecture any advantage that is gained by the close resemblance between an African Euphorbia and a South American Cactus, the imitation being carried out in the most extraordinary manner throughout the vegetative organs, the flowers being, of course, totally unlike.

But besides these superficial resemblances, there are also analogies of organic structure in different classes of the animal kingdom, which Mr. Mivart holds to be equally opposed to the theory of Natural Selection. He refers especially to the existence of the higher organs of sense, as the eye, in at least three distinct and independent lines of descent, the Mollusca, the Annulosa, and the Vertebrata, an objection already pointed out by Mr. Murphy; to the resemblance between the shells of certain Mollusca and Crustacea, the valve being moved in each case by analogous muscles; to the analogy between the different families of Marsupials and the different orders of Placental Mammals; and to numerous other instances. These might be supplemented in the vegetable kingdom by the similarity in the mode of opening of the anthers in Berberidaceæ and Lauraceæ, or the extraordinary resemblance of certain Conifers to flowerless plants. The wood-cuts which we give illustrate the remarkable resemblance between an ordinary European mouse and an Australian marsupial (Fig. 2); the structure of the cuttle-fish with the brain, cartilaginous cranium, and complex auditory nerve, presenting so many similarities to those of the higher Vertebrata, and yet belonging to a different line of descent (Fig. 3); and the curious bird's-head-like processes found in some of the higher Polyzoa (Fig. 4)

Of exceptional structures, none is more interesting in a philosophical point of view than the neck of the giraffe. This has been explained on Darwinian principles from the occurrence in its native country of occasional periods of drought, during which those giraffes only have survived which had the power of reaching somewhat higher branches of the trees; and this peculiarity, being advantageous, was propagated, and continually augmented during each period of drought by the process of Natural Selection. To this Mr. Mivart objects, firstly, that if this explanation is correct, many other African animals, which have no greater power of endurance or of migration than the giraffe, ought to have elongated necks; and secondly, that in the intervals between the droughts the long neck would be a positive disadvantage, as requiring a greatly increased size and strength of muscles to support it, and would, consequently, be lost before the next drought set in. To take another instance of the commencement of an organic structure which is universal in all the higher classes of animals; there is scarcely anything more inexplicable than the separation of the sexes, if we suppose animals with distinct sexes to have originated by the process of Natural Selection from those simple forms which propagate by cell-multiplication or spontaneous fission.

FIG. 4 —A Polyzoon with Bird's-head Processes.

FIG. 5.—An Annelid dividing spontaneously.
(A new head having been formed towards the hinder end of the body of the parent.)

We have not space to enumerate all our author's arguments, for which we must refer our readers to the volume itself, wherein even those who differ from his conclusions will find a mine of physiological information and ingenious speculation. Nor can we do more than allude to the theological portion of the work, wherein he ably defends the doctrine of Evolution against both the *odium theologicum* and the *odium antitheologicum.*

The present state of the argument we take to be this :—The theory of Natural Selection, in the hands of Mr. Darwin and Mr. Wallace, afforded a simple, a beautiful, and a valid solution of the origin of a large number of the organic phenomena by which we are surrounded ; by many disciples of Mr. Darwin it has been assumed, perhaps too rashly, as adequate to account for the entire evolution of all the existing forms of animal and vegetable life from one or a few primordial germs. To this idea, so seductive in its very simplicity, a number of more or less cogent objections have now been urged. It is possible that on still closer examination, these objections will be found to break down ; but in the meantime we must suspend our judgment ; and in order to save defeat, the next move must be made by the advocates of Natural Selection, a *primâ facie* case against them having at all events been made out. Mr. Mivart has no counter theory to propose, beyond a belief that there exists in all organic life an innate power analogous to intelligence, which controls their actions as reason does those of men. Should the inquiries which are now being energetically pursued on every side result in our acquiring more accurate knowledge of such a force, it will be safe to predict that to it will then be ascribed a more easy and natural solution of many phenomena which we are now forced to attribute to Natural Selection.

ALFRED W. BENNETT

NOTES

THE Royal Commission on Scientific Instruction and the Advancement of Science is about to resume its sittings, and meetings will be held at 6, Old Palace Yard, Westminster, on Thursday, February 9 ; Friday, February 10 ; Monday, February 13 ; Tuesday, February 14, at 11.30 A.M.

IN the recent changes which have taken place in the Royal Mint by the deaths of Professors Graham and Miller, Dr. Stenhouse, F.R.S., lost his position as Non-resident Assayer to the establishment. Several of our leading chemists, including Sir Benjamin Brodie, and Professors Williamson, Frankland, and Odling thought that this was an opportunity for recognising the services which Dr. Stenhouse had rendered to chemistry by his numerous researches, and they requested Dr. Lyon Playfair, M.P., to bring his claims before the Premier. We have now the gratification to announce that the representation has been successful, and that Her Majesty has directed that a pension on the Civil List of 100*l.* should be given to Dr. Stenhouse "in consideration of his scientific attainments."

THE shelling of Paris has been disastrous to M. Desnoyers, the librarian of the Museum, who lost his son by it. The celebrated Abbé Moigno, editor of *Les Mondes*, was slightly hurt by the breaking of a glass, from an explosive shell. The private apartment of M. Milne-Edwards was visited by a shell which has done much harm to the valuable furniture. Another shell penetrated into the Gallery of Zoology and caused much damage to the glass-work ; and again another into the Gallery of Mineralogy, in the very place where M. Daubrée performs his experiments on artificial meteors ; but happily it had exhausted its force, and did but little harm. Many instances of this description have occurred, where shells were sent to their utmost range, and did not explode under such circumstances. The reverse has however been observed, for one shell falling in the Seine with great force, the water offered resistance like a solid body, and explosion took place : the effect was curious. A shell fell in the courtyard of the Collège de France when M. Levavasseur was lecturing on political economy, and the young professor was not disturbed by the projectile, portions of which broke through the windows. He continued lecturing, saying, "Those who fear such things have only to leave the place."

THE addition to the building for the Museum of Comparative Zoology at Cambridge, at an expense of upwards of 60,000 dollars, is rapidly going on. Prof. Agassiz has returned to Cambridge with restored health, and with new plans for the enlargement of his museum. Prof. O. C. Marsh, of Yale College, has just returned with his party from the Rocky Mountains.

THE *Indépendance Belge*, in its number for January 9, publishes an extract from the *Comptes-rendu de l'Académie des Sciences*, in which M. Elie de Beaumont describes the experiments used in directing the course of the balloon which fell at Rheims. In accordance with what was said in one of our recent numbers, M. Elie de Beaumont, who had witnessed the ascent, explained to his colleagues that the wind was bearing to the East, but that owing to the deviation the balloon would reach Switzerland! He was, however, most unfortunate. The captain of the directing balloon arrived recently at Lille. Experiments directed by M. Mangon have proved that a balloon 90,000 cubic metres measurement requires forty-two foot-pounds to move with a rapidity of a yard per second, which is a very important result for future experiments. The mass of gas and balloon is about three tons.

MR. J. HOPKINSON, the Senior Wrangler of 1871, is a native of Manchester. He was educated at Owens College; and at Easter 1867 obtained the Senior Mathematical Scholarship at Trinity, after open competition. In 1868 he also obtained the Sheepshanks Astronomical Scholarship. In 1867 he was awarded the exhibition in Chemistry and Natural Philosophy, at the first examination for the B.Sc. degree at the London University; and at the second examination for the same degree in the following year he carried off the Scholarship in Mathematics and Natural Philosophy. Mr. Jas. W. L. Glaisher, the Second Wrangler, is the son of Mr. Jas. Glaisher, F.R.S., director of the Meteorological Department at the Greenwich Observatory. He received his education at St. Paul's School, where he gained the first mathematical prizes in 1865, 1866, and 1867. On leaving school he entered Trinity College with a Senior Campden Exhibition. He is the author of a paper read before the Royal Society in March 1870, on the numerical value of the sine-integral, cosine-integral, and exponetical-integral.

THE Delegate Government of Bordeaux has established a Scientific Commission, presided over by M. Marié Davy, the meteorologist, and having amongst its members the Professor of Analysis at the Polytechnic School of Paris, M. Silberman, Head of the Physical Laboratory at the Collège de France, and some local scientific celebrities.

M. LEVERRIER is said to be hiding in a country place near Marseilles, assuming a false name, and living like a private man with one of his intimate friends.

M. THÉNARD, a member of the French Institute, who had retreated to his home on the Côte d'Or, was taken prisoner and sent to a fortress in Germany as a hostage. The President of the French Institute has protested against the arrest. M. Thénard is the son of the celebrated Professor of Chemistry, and belongs to the agricultural section. He is a landed gentleman of considerable property.

THE elephants and other animals of the same description at the *Jardin des Plantes* were sacrificed to the necessities of the war. Members of the French Institute were present on the spot in order to witness the effects of the shots on the huge brutes, and some parts of the body were set apart for careful dissection. M. Milne-Edwards has taken advantage of the circumstance to prepare a paper, which must have been already presented to the French Institute, and which will create a sensation in the scientific world.

DURING last session the American Congress made an appropriation of 50.000 dollars for Arctic exploration, with the promise that the scientific operations of the expedition were to be prescribed by the National Academy of Sciences. Captain Hall was appointed by the President of the United States to command the expedition in question, and a commission of the National Academy, recommended by Professor Henry, is to act in concert with him, and to prepare a manual of scientific inquiry for the use of the expedition, "which will, undoubtedly," says the *American Naturalist*, "interest a large circle of readers when published."

MR. A. HYATT has been appointed Professor of Palæontology at the Massachusetts Institute of Technology. Mr. E. S. Morse has been chosen Professor of Comparative Anatomy and Zoology at Bowdoin College, and has been appointed lecturer in the same branch at the Maine Agricultural College. Dr. A. S. Packard, jun., editor of the *American Naturalist*, is to lecture on Economic Entomology at the same institution. Mr. B. H. Emerson has recently been elected Professor of Geology at Amherst College, the chair filled for so many years by Dr. Edward Hitchcock, sen.

THE *American Naturalist* states that Dr. Hagen has recently returned from Europe, having purchased, through funds supplied by a lady in Boston, for the Cambridge Museum, a Parisian collection of weevils of great extent and value. He has also brought over his own unrivalled collection of Neuroptera. Its presence in the United States is most fortunate for this department of entomology. The same journal gives us the following additional items of entomological intelligence:—Congress is about to print an entomological report by Townend Glover, the entomologist of the Agricultural Department. It will form an exceedingly useful work, and will deserve the widest circulation. Mr. P. R. Uhler, of Baltimore, has ready for publication by the Boston Society of Natural History, descriptions of the Hemiptera of the Harris entomological collection. Gradually the unpublished results of the labours of Dr. T. W. Harris are being given to the public.

MR. J. A. M'NIEL, who has made two expeditions to Central America, is now in Philadelphia preparing for a third archæological excursion to Nicaragua.

IN the number of the *Quarterly Journal of Education* for January is a short article on school books, in which occur the following remarks, which we commend to the notice of these interested:—"The vast majority of elementary works are written specially as aids to assist the student in cramming a certain specified subject, so that he shall be able to pass some particular examination. Now every examination differs to a certain extent from any other examination, and text-books are therefore required to point out and elucidate these differences. For example, one is told that it is almost imperative to use Buckmaster's Chemistry in preparing for the science examinations, whilst Miller's, Williamson's, Gill's, or Barff's works upon the subject, although admitted by competent authorities to be the best of their kind, are kept in the background. On the other hand, in preparing for the London University examinations, it is better to use the latter works. . . . Frequently, again, an examiner writes and publishes a text-book, and, of course, he has a predilection for the peculiarities of his own offspring; and, by so framing his questions that a knowledge of *his* book is necessary, he increases its sale, and thereby the balance at his banker's." Without subscribing to the inuendo contained in the last sentence, we think the *Journal* here points out a weak place in our examination-system. Great complaints are made—and these do not come from rejected candidates—that the mode in which questions are sometimes put at these examinations renders them impossible to be answered clearly by any student who has not been trained in the particular school of the examiner, though he may possess a competent knowledge of the subject. This is a great evil, and ought to be looked into.

WE have received the first four numbers of what seems likely to be a very useful series of publications issued by authority of the University of New Haven, Connecticut, and termed "The University Series." Two of these are reprints of the well-known English treatises:—Prof. Huxley "On the Physical Basis of Life," and Dr. Jas. H. Stirling "As Regards Protoplasm, in reference to Prof. Huxley's Essay." The remaining two comprise Prof. Cope's essay "On the Hypothesis of Evolution, Physical and Metaphysical;" and Prof. G. A. Barker of Yale College "On the Correlation of Vital and Physical Forces."

A RECENT number of *L'Illustration Horticole* contains an interesting paper on the Botanic Gardens of Kew, by M. André, prefaced by some details regarding similar establishments in Europe. From this it appears that the first was established at Padua in 1545, followed by that of Pisa; those of Leyden and Leipzig date respectively 1577 and 1579. The Montpellier garden was founded in 1593, that of Giessen in 1605, of Strasburg in 1620, of Altorf in 1625, and of Jena in 1629. The Jardin des Plantes was established in 1626, and the Upsal Garden in 1627; that of Madrid dates from 1763, and that of Coimbra from 1773. At the end of the eighteenth century, according to Gesner, more than 1,600 kindred establishments existed in Europe. England comes late in the list, the Oxford Garden not having been founded until 1632, and long remaining the only one in the kingdom.

WE learn from the *Scottish Naturalist* that the work of fitting up cabinets for the reception of the Natural History collection in the Paisley Museum is rapidly approaching completion; and that the opening is expected to take place shortly. The geological and botanical specimens are mostly, if not all, British, and will form a valuable reference collection for students. The large and valuable reference library will contain a choice selection of scientific works.

THE revenue cruiser *Moccasin*, according to the *Technologist*, has been supplied with a new marine drag, that is, one of those substitutes for an anchor which will, it is said, effectually prevent a ship's drifting even in the heaviest weather. The success of experiments made and reported to the Treasury department has caused a contract to be made with a New York firm for the construction of several of these marine drags; and it is the intention to supply all vessels in the Revenue service with them. To vessels off a lee shore, in stormy weather, the marine drag must be a most desirable protection against shipwreck.

SINCE the American publishers abandoned the reprinting of the *Chemical News*, our American friends, says the New York *Technologist*, "have no resource but to subscribe for the original London edition. We do not regret this. What they lose in cost they more than gain in neatness and accuracy, and also in the fact that they do not have to wait a month for their news."

MR. ANDREW MURRAY has published in the *Field* some remarks upon eight samples of honey which have been forwarded by M. de Solsky, of the Agronomic Museum of St. Petersburg, to the South Kensington Museum. The honey was produced by bees fed in districts where there was a great preponderance of the following plants:—*Reseda odorata* (mignonette), *Tilia parvifolia, Dracocephalum moldavicum, Carduus nutans, Fagopyrum esculentum* (buckwheat), *Epilobium angustifolium, Echium vulgare*, each plant being represented by one of the samples. The eighth consisted of honey flavoured by the herbs of the Steppes of Central Russia, and this was the best of all in taste. Next came that from the mignonette, then that of the lime-tree; the buckwheat honey being beyond question the worst.

ONE of the most interesting and important trees of Sumatra is the Camphor-tree, *Dryobalanops camphora*. This camphor attracted the attention of the earliest voyagers, and was then, as it is now, an important article of commerce with China and Japan, the people of those countries attributing to it extraordinary virtues and paying a high price for it. The tree grows to a height of 100 or 130 feet, and forms a trunk 7 to 10 feet in diameter. The quantity of camphor contained in the trunks is very unequal, the young trees appear to contain little or none. It is said that, on an average, about nine trees are required to produce 100 lbs. weight of crystallised camphor. It is obtained by cutting down the tree and dividing the wood into small pieces, in the divisions of which the camphor is found. It differs in the form of its crystals from the camphor of commerce, is harder, more brittle, and does not so readily condense. Great quantities are used by the Bataks for the preservation of the corpses of their chiefs. The trees are spread over a portion only of Sumatra and Borneo, and generally occur in localities into which commerce and civilisation have as yet but little penetrated. Notwithstanding the continued destruction of the trees, for the sake of procuring the camphor, no means are taken for the future preservation of the species. This camphor is seldom seen in this country, except in museums. The Chinese eagerly buy it in preference to the ordinary camphor—their own produce—which they send in such large quantities into the European markets.

THE habit of branching among palms, though constant only in the Doum palm (*Hyphæne thebaica*) of Egypt, is not uncommon in other genera, and notably amongst Palmyras (*Borassus flabelliformis*) and Cocoa Nuts, (*Cocos nucifera*), figures and descriptions of which have been published in the Linnean Society's Transactions. According to a correspondent in Ceylon, branching Cocoa Nuts, Palmyras, and Arecas, are to be seen there in plenty, besides other curious freaks of the Cocoa Nut, such, for instance, as the growth of two or three trees from one nut. In the Racket Court at Colombo, we are told that five trees are now flourishing (or at least were at the time the letter was written) which have proceeded from the same nut. Originally there were eight in all, but three have died, probably by the nourishment being drawn away from them for the sustenance of the other five.

THE use of the fruits of *Taughinia venenifera* in Madagascar as an ardent poison is of great antiquity, and is one of the still remaining superstitious customs ardently believed in by savage nations. The system of administering the poison has been often told, but the following account from a private letter of an eye-witness differs in so many points from those we have before read that we give it entire. The fruit was taken, bruised, and boiled whole. A fowl was boiled, and the broth set aside. Three pieces of the skin of the fowl were cut and put into the broth; a cupfull of poison was first administered, followed by another of the broth containing the three pieces of skin. If vomiting did not speedily set in, the poison soon killed, but if it did, it was kept up by constant exhibition of the broth and warm water until the three pieces of skin were ejected. Should the skins obstinately remain, it was held as evidence of guilt, and another dose of the poison was administered.

SOME discussion has taken place in Indian circles on the authenticated, but unprecedented, fact of a tigress having been shot near Octacamund, by Colonel Christie, while she was forty feet from the ground in a tree. Many observers state that a tiger when in danger, and at the foot of a tree, does not take to a tree, and in the inundations only gets on to the lower branches. A leopard does take to a tree.

HEAT SPECTRA

I NOTICE in NATURE, vol. i., p. 28, an account of some very important researches on Heat Spectra, made by the late Professor Magnus; and I am gratified to think that some observations which I made on the subject in the years 1858 and 1859 were confirmed by this eminent German philosopher.

In a paper read before the Royal Society of Edinburgh in 1858, I showed that rock-salt absorbs heat radiated from rock-salt in larger quantity and more powerfully than other kinds of heat; and also that the amount of absorption of rock-salt for heat increases with the thickness of the absorbing plate. These are the fourth and fifth results of Professor Magnus. His next result is very interesting, namely, that the high diathermancy of rock-salt does not depend on its small absorptive power for the different kinds of heat, but on the fact that it only radiates, and consequently only absorbs, heat of one kind; while almost all other bodies at the temperature of 150° F., emit heat which contains only a small fraction or none of those rays which are given out by rock-salt.

Certain experiments which I made in 1859 lead me to think that Professor Magnus was quite justified in his conclusion that the heat radiated and absorbed by rock-salt is a peculiar kind of heat. These experiments, which are described in the Transactions of the Royal Society of Edinburgh, are as follows. I tested the quality of the heat radiated by rock-salt at 212° F. by transmitting it through three different screens:—

α A screen of mica.
β One of mica split by heat.
γ One of glass.

It was found that a mica screen, which passed about 31 per cent. of ordinary lampblack heat, passed only 18 per cent. of rock-salt heat; or if we call the proportion of black heat passed by the mica 100, that of rock-salt heat will be 58. Again, it was found that while 20 per cent. of lampblack heat passed through a screen of split mica, the proportion of rock-salt heat transmitted through the same screen was only 15¼ per cent. These numbers are to one another as 100 to 76.

Lastly, with respect to a glass screen, calling the proportion of lampblack heat which passed 100, that of the rock-salt heat which passed the same screen was 57.

On these results I remark as follows:—It is already well known that rays of great refrangibility, or small wave length, pass through glass or mica more readily than those of an opposite character. The difficulty with which rock-salt heat penetrates these substances as compared with ordinary heat, might therefore lead us to infer that the wave length of this heat is greater than that of ordinary lampblack heat.

If we now look to the relative transmission of the two descriptions of heat through mica split by heat, we see that the facility of transmission is yet in favour of ordinary heat, but not so strikingly as with a screen of common mica. This will be seen from the following table:—

Nature of Screen	Transmission of Ordinary Heat at 212°	Transmission of Rock-salt Heat at 212°
Mica	100	58
Mica split by heat	100	76

Compare this with the following table, deduced from the results given by Professor Forbes:—

Nature of Screen	Transmission of Heat from Blackened Brass at 700° F.	Transmission of Black Heat at 212° F.
Mica ·015 inch thick	100	52
Mica split by heat	100	64

From a comparison of these two tables, it will be seen that, as tested by the two substances, mica and mica split by heat, rock-salt heat at 212° F. bears to ordinary heat of that temperature a relation similar to that which ordinary heat at 212° bears to heat at 700°; that is to say, that just as heat of 212° has a greater wave-length than heat of 700°, so rock-salt heat at 212° has a greater wave-length than ordinary heat at that temperature. And the *surface stoppage* produced by splitting the mica, telling most powerfully upon heat of high temperature, or small wave-length, while the *stoppage* by *substance* is in the opposite direction, we see how the one effect tends, to a certain extent, to neutralise the other, rendering the proportions of different kinds of heat passed by split mica more nearly alike than those passed by ordinary mica. In connection with these remarks I may state that neither the radiation nor the absorption of a plate of rock-salt is sensibly influenced by roughening its surface with emery paper.

All these experiments concur in showing that heat from rock-salt possesses very great wave-length, and probably heat from a thin plate of this substance, at a low temperature, may be found to possess a greater wave-length than any other description of heat which can be exhibited.

The observations of Professor Magnus with respect to the nature of the heat from potassium chloride are very interesting; unfortunately I did not make any experiments on this substance, but I did on some others in the shape of powder.

I found that the comparative radiation at 212° was as follows:—

From lamp black	100
Alum in powder	100
White sugar	98·7
Sulphate of potash	88·1
Nitrate of potash	86·7
Table salt	83·1

The experiments of Prof. Magnus on the reflection of heat are also of the very greatest importance, and they strengthen the evidence (already overwhelming) in favour of that view which regards light and heat as varieties of the same agent differing in nothing except wave-length.

BALFOUR STEWART

*ON THE METHOD OF ASSAYING SILVER AS CONDUCTED IN THE INDIAN MINT**

BY DR. H. E. BUSTEED, OFFG. ASSAY MASTER

THE method of assaying silver, as now in use in H.M.'s Indian Mints, is one peculiar to them; it was introduced into the Calcutta Mint about the year 1850, and thence extended in course of time to those of Bombay and Madras.

It has been favourably reported on and described more or less in detail as an official duty by various assay officers to local Mint authorities in India; but beyond this it would appear that no attempt has been made towards giving publicity to the practical working of the process, or to making generally known the laboratory details of this method of assay.

It has been suggested to the writer that some such attempt now would be not only interesting but useful, as after twenty years' experience of it, the assay offices in the Indian Mint must be in a position to assign its true value to a method which has been used for the assay of an immense importation and coinage of silver bullion. To render it more generally intelligible, and to show wherein the process about to be explained contrasted with those in more general use, Dr. Busteed very briefly adverted to the principles on which those processes depend for their results, omitting details and technicalities. In modern acceptance, the principal duty of an assayer is to ascertain the proportion of the precious metals present in any sample of mixed metal submitted to him for examination, so that from the result of his investigation the proper value may be assigned by calculation to the mass which the sample is supposed to represent.

This the assayer effects by separation of the precious metals from the coarser ones. The most ancient means of effecting this was by the method of *cupellation*. He explained the principle of this method, what skill and experience it required on the part of the operator, and how it still fell short of accuracy in its results.

* From the Proceedings of the Asiatic Society of Bengal.

Its shortcomings led to the invention of another process by Gay-Lussac, known as the volumetric, or humid, method, which is much more accurate, and is now practised very generally on the Continent. Its principles were briefly glanced at. Its introduction, however, into the Indian Mints was not considered desirable by their assay officer for certain reasons, a few of which were given. The method of cupellation, therefore, being not accurate enough for the purposes of buying and selling bullion, and that by the French process being considered not well suited to Indian Mints, it became necessary to look out for and introduce into the Mints of this country a process more likely to answer all the ends in view.

This object was attained by the adaptation and introduction of the process now in use, viz. the "Chloride process of assaying silver.' Hitherto it had never been resorted to, except on a very small scale. Assayers appear to have shrunk from the manifest difficulties of manipulation in collecting, drying, and weighing the precipitated chloride of silver. The credit is due to Mr. James Dodd, a former Assay Master of the Calcutta Mint, of having so simplified, modified, and systematised the details of this method, as to render its application to the assaying of silver on a large scale easy and accurate. The principles, and an outline of the details of the process were then given, an understanding of some of the chief appliances and steps in the manipulations being assisted to by suitable photographs. The system of weights in use, and the quantity of the sample taken for assay, were also explained, as well as the points wherein this system might fairly be considered better suited to a Mint in India than the other methods.

In conclusion Dr. B. alluded to the vast amount of silver bullion which this process enabled the assay officers of the Indian Mints to deal with confidently and accurately during the past fifteen years. In one year alone, that of 1865-66, the importation of silver bullion reached to the immense amount of over fourteen millions sterling, so putting to a crucial test the system of assay used for its valuation.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 12.—"On Fluoride of Silver," Part II., by George Gore, F.R.S. An exhaustive account of the behaviour of argentic fluoride in vessels of platinum, carbon, and various fluorides in contact with chlorine, bromine, and iodine at various temperatures. When argentic fluoride is completely decomposed by chlorine in platinum vessels at a red heat, the reaction agrees with the following equation :—

$$4\,Ag\,F + 4\,Cl + Pt = 4\,A\,G\,Cl,\ Pt\,F_4.$$

Vessels of cryolite and of fluor-spar were found incable of retaining argentic fluoride in a melted state. Other vessels were also made by melting and casting various mixtures of earthy fluorides at a high temperature; and although forming beautiful products, probably capable of technical uses, they were not capable of retaining silver fluoride in a state of fusion. Numerous vessels were also made of seventeen different fluorides by moulding them in the state of clay and baking them at suitable temperatures; these also were found incapable of holding melted fluoride of silver. Argentic fluoride was only superficially decomposed by chlorine at 60° Fahr. during thirty-eight days. When heated to 230° Fahr. during fifteen days in a platinum vessel in chlorine, it was very little decomposed. Chloride of silver heated to fusion in a platinum vessel in chlorine corroded the vessel and formed a platinum-salt, as when fluoride of silver was employed. An aqueous solution of argentic fluoride agitated with chlorine evolved heat and set free oxygen, in accordance with the following equation :—

$$8\,Ag\,F + 8\,Cl + H_2O = 5\,Ag\,Cl + 3\,Ag\,Cl\,O + 8\,H\,F + O,$$

or

$$7\,Ag\,Cl + Ag\,Cl\,O_3 + 8\,H\,F + O.$$

Dry hydrochloric acid gas completely decomposed argentic fluoride in a melted state, but only acted upon it superficially at 60° Fahr. A saturated aqueous solution of argentic fluoride was not precipitated by chloric acid. Perfectly anhydrous fluoride of silver was only superficially decomposed by contact with bromine in a platinum vessel during thirty-six days at 60° Fahr., or during two days at 200° Fahr. At a low red heat in vessels of platinum argentic fluoride was completely decomposed by a current of bromine vapour, a portion of its fluorine being expelled and a portion corroding the platinum and forming an insoluble compound of fluoride of platinum and bromide of silver. In carbon boats at the same temperature the whole of the silver-salt was converted into bromide, the boat being corroded and the fluorine escaping in chemical union with the carbon. The action of bromine on an aqueous solution of argentic fluoride was similar to the action of chlorine. A solution of argentic fluoride yielded copious precipitates both with hydrobromic and bromic acids. Under the influence of a temperature of 200° to 600° Fahr. in closed platinum vessels, iodine very slowly and incompletely decomposes argentic fluoride without corroding the vessels, and produces a feeble compound of argentic iodide, fluorine, and iodine, from which the two latter substances are expelled at a red heat. At a red heat in platinum vessels, iodine produces argentic iodide, and in the presence of free argentic fluoride corrodes the vessels in consequence of formation of platinic fluoride; iodine and fluorine pass away together during the reaction. In vessels of carbon at the same temperature, argentic iodide is formed, the vessels are corroded, and a gaseous compound of fluorine and carbon is produced. By treating an aqueous solution of argentic fluoride with iodine, similar results are produced as with bromine and chlorine; a similar solution yields copious precipitates both with hydriodic and iodic acids. A mode of analysis of iodine is also fully described in the paper. A known weight of iodine was dissolved in absolute alcohol, a strong solution of argentic nitrate of known strength added to it in proportions at a time with stirring until the colour of iodine exactly disappeared. The mixture was evaporated, the free nitric acid expelled by careful heat, and the residue weighed. The residue was then heated to fusion to convert the iodate of silver into iodide, and again weighed. Two experiments of this kind yielded accurate results, and the process was easy and expeditious.

January 19.—"On the Structure and Development of the Skull of the Common Frog (*Rana temporaria*)," by W. Kitchen Parker, F.R.S. At the close of my last paper, "On the Skull of the Common Fowl," I spoke of bringing before the Royal Society another, treating of that of the osseous fish. I was working at the early conditions of the salmon's skull at the time. I was, however, led to devote my attention to another and more instructive type early in the following year; for it was then (January 1869) that Professor Huxley was engaged in preparing his very important paper "On the Representatives of the Malleus and Incus in the other Vertebrata" (see Zool. Proc. May 27, 1869). In repeating some of his observations for my own instruction, it occurred to me to renew some researches I had been making from time to time on the frog and toad. The results were so interesting to us both, that it was agreed for me to work exhaustively at the development of the frog's skull before finishing the paper on that of the salmon. On this account Professor Huxley mentions in his paper (*op. cit.* p. 406) that he leaves the Amphibia out of his demonstration, and that they are to be worked out by me. The amount of metamorphosis demonstrable in the chick whilst enclosed in the egg, suggested a much more definite series of changes in a low, slow-growing Amphibian type. I think that this has been fully borne out by what is shown in the present paper.

The first of the ten stages into which I have artificially divided my subjeet is the unhatched embryo, whilst its head and tail project only moderately beyond the yelk-mass. Another stage is obtained by taking young tadpoles on about the third day after they have escaped from their glairy envelope; a few days elapse between the second and third stages, but a much longer time between the third and fourth, for the fourth stage is the perfect tadpole, before the limbs appear and whilst it is essentially a fish with mixed Chimæroid and Myxinoid characters. Then the metamorphosing tadpole is followed until it is a complete and nimble frog, two stages of which are examined, and then old individuals are worked out, which give the culminating characters of the highest type of Amphibian.

The early stages were worked out principally from specimens hardened in a solution of chromic acid; and the rich umber-brown colour of these preparations made them especially fit for examination by reflected light.

Without going further into detail as to the mode of working my subject out, and without any lengthened account of the results obtained, I may state that the following conclusions have been arrived at, namely, that the skull of the adult is highly compound, being composed of :—

1st. Its own proper membranous sac;

2nd. Of a posterior part which is a continuation, in an unsegmented form, of the vertebral column;

3rd. Of laminæ which grow upwards from the first pair of facial arches, and which enclose the fore part of the membranous sac, just as the "investing mass" of the cranial part of the notochord invests the hinder part;

3rd. The ear-sacs and the olfactory labyrinth become inextricably combined with the outer case of the brain.

And 5th. The subcutaneous tissue of the scalp becomes ossified in certain definite patches; these are the cranial roof-bones. Around the mouth there are cartilages like those of the Lamprey and the Chimera; but these yield in interest to the proper facial bars, which are as follows, namely:—

First pair the "trabeculæ."

Second pair the mandibular arch.

Third pair the hyoid arch.

And fourth to seven pairs; these are the branchials.

These are all originally separate pairs of cartilaginous rods; and from these are developed all the complex structures of the mouth, palate, face, and throat. The pterygo-palatine arcade is merely a secondary connecting bar developed, after some time, between the first and second arches.

Meckel's cartilage arises as a segmentary bud from the lower part of the second; and the "stylo-cerato-hyal," as a similar secondary segment, from the third arch.

By far the greater part of the cranium (its anterior two-thirds) is developed by out-growing laminæ from the trabeculæ, which after a time become fused with the posterior or vertebral part of the skull.

When the tadpole is becoming a frog, the hyoid arch undergoes a truly wonderful amount of metarmophosis.

The upper part, answering to the hyomandibular of the fish (not to the whole of it, but to its upper half), becomes the "incus," and a detached segment becomes the "orbiculare," which wedges itself between the incus and the "stapes." The stapes is a "bung" cut out of the "ear-sac." The stylo-cerato-hyal is set free, rises higher and higher, and then articulates with the "opisthotic" region of the ear-sac; in the toad it coalesces therewith, as in the mammal. The lower part of the hyomandibular coalesces with the back of the pier of the mandibular arch; and the "symplectic" of the osseous fish appears whilst the tadpole is acquiring its limbs and its lungs, and then melts back again into the arch in front; it is represented, however, in the Bull-frog, but not in the common species, by a distinct bone.

This very rough and imperfect abstract must serve at present to indicate what has been seen and worked out in this most instructive vertebrate.

"Modification of Wheatstone's Bridge to find the Resistance of a Galvanometer Coil from a Single Deflection of its own Needle." By Professor Sir W. Thomson, F.R.S. In any useful arrangement in which a galvanometer and a galvanic element or battery are connected through whatever trains or network of conductors, let the galvanometer and battery be interchanged. Another arrangement is obtained which will probably be useful for a very different, although reciprocally related, object. Hence, as soon as I learned from Mr. Mance his admirable method of measuring the internal resistance of a galvanic element (that described in the first of his two preceding papers), it occurred to me that the reciprocal arrangement would afford a means of finding the resistance of a galvanometer coil, from a single deflection of its own needle by a galvanic element of unknown resistance. The resulting method proves to be of such extreme simplicity that it would be incredible that it had not occurred to anyone before, were it not that I fail to find any trace of it published in books or papers, and that personal inquiries of the best informed electricians of this country have shown that in this country at least it is a novelty. It consists simply in making the galvanometer coil one of the four conductors of a Wheatstone's bridge, and adjusting, as usual, to get the zero of current when the bridge contact is made; with only this change of plans, that the test of zero is not by a galvanometer in the bridge itself showing no deflection; but by the galvanometer, the resistance of whose coil is to be measured, showing an unchanged deflection. Neither diagram nor further explanation is necessary to make this understood to anyone who knows Wheatstone's bridge.

Chemical Society, January 19.—Professor Odling, F.R.S., Vice President, in the chair. The following gentlemen were elected fellows:—R. Bannister, H. T. Brown, J. Moss, R. J. Moss, E. Potts. The following papers were read:—"On the action of sulphuric acid on the natural alkaloids," by Henry E. Armstrong. On heating narcotine with sulphuric acid, which had previously been diluted by its own volume of water over the water-bath, and subsequent addition of ammonia to the mixture, a body is obtained which shows at once the properties of dimethylnarcotine, the base which Matthiessen and Wright had obtained from narcotine by means of hydrochloric acid. The reaction takes place, therefore, according to the equation—

$$C_{22}\,H_{23}\,N\,O_7 + H_2\,S\,O_4 = C_{21}\,H_{21}\,N\,O_7 + C\,H_3\,H\,S\,O_4.$$

From this result the author concludes it becomes evident that Gerhardt and Laurent's view, who regarded this body as an amide, must be abandoned. On treating codeine in a similar manner, and dissolving the base obtained in hydrochloric acid, a crystalline hydrochlorate was obtained. An analysis of the product showed it to be hydrochlorate of codeine. The first action of sulphuric acid results, therefore, in the production of an isomeric codeine. By the further action of sulphuric acid, 1 molecule of water is removed from 2 of codeine—then 1 H_2O from 1 codeine, and finally, apomorphine seems to be formed. On this last point, however, further evidence has yet to be awaited. "On the origin of nitrates in potable waters," by Ch. Ekin.—The author found nitric acid in the water of a spring which is very remote from any agency that could impart to it decaying animal matter. On closer examination, he found that the water in question had passed through a fossiliferous stratum. This observation necessitates a modification of the "previous sewage contamination theory."—"On an alkaloid from Cinchona bark, hitherto undescribed," by Dr. Howard. This new alkaloid was obtained from the mother liquors of quinine salts. It is a yellowish oil which cannot be sufficiently purified for analytical purposes. The formula of its platino-chloride corresponds with the formula assigned by Gerhardt to the anhydrous platino-chloride of quinine. Mr. Macleod exhibited an ingenious little contrivance by means of which eudiometer tubes which have lost the outer portion of their discharging wires may yet be made use of.

Mathematical Society, January 12.—Mr. W. Spottiswoode, F.R.S., President, in the chair. The Rev. J. Wolstenholme, M.A., Christ's College, and Mr. R. B. Hayward, M.A., late Fellow of St. John's College, Cambridge, were proposed for election. There was a large attendance of members to hear Prof. Peirce, of Harvard, give an account of the methods made use of in his "Linear Associative Algebra." The President conveyed to the author the thanks of the society for his interesting communication. Other papers communicated were "On Systems of Tangents to place Cubic and Quartic Curves," by Mr. J. J. Walker, M.A., and "On the Order and Singularities of the parallel of an Algebraical Curve," by Mr. S. Roberts, M.A. In the course of the evening Mr. Roberts stated the following construction as being mechanically more convenient than one discussed in a former paper "On the Pedals of Conics:"—In a plane, if a limited straight line, whose length is equal to the distance between the centre of two equal circles, moves with an extremity on each, the locus of any point rigidly connected with the line will consist of a circle, and a bi-circular quartic with a third node.

Entomological Society, January 23.—At the Annual Meeting this day held, Mr. A. R. Wallace, President, in the chair, the following gentlemen are elected to form the Council for 1871.—Messrs. Butler, Dunning, Fry, Grut, Higgins, M'Lachlan, Major Parry, Pascoe, E. Saunders, Stainton, S. Stevens, A. R. Wallace, and Professor Westwood. The following officers for 1871 were subsequently elected:—President, Mr. A. R. Wallace; Treasurer, Mr. S. Stevens; Secretaries, Messrs. M'Lachlan and Grut. Librarian, Mr. Janson. An Address was read by the President, which will be published *in extenso* in the Society's Proceedings.

Ethnological Society, January 24.—Professor Huxley, President, in the chair. The Rev. Dr. Steere read a paper "On the Tribes and Languages of East Africa." The author, who had resided for several years at Zanzibar, described in detail the Swahilis, a mixed race, half negro and half Arab, belonging to the Shafi school of Mahommedans. Many examples of their folk-lore were introduced, and a detailed description was given of the Swahili language. A comparison was instituted between the Swahili, Shambala, Yao, and Nyamwezi languages, which all belong to the great Bântu family. Mr. Hyde Clarke spoke upon this communication.—A paper was read "On the weapons and implements used by the Kaffir Tribes and Bushmen of South Africa," by Dr. Carl L. Griesbach. The author described the primitive method of iron-smelting practised by the Kaffirs, and alluded to the knowledge of certain mixed metals, such as brass, possessed by some of the northern tribes. A description was also given of the native method of gold-washing, carried on in some of the tributaries to the Zambesi. The degraded state of the Bushmen was referred to, and it was remarked that although they are ignorant of iron-working, they yet possess some artistic taste. Among the South African implements attention was directed to the musical instruments, which the author considered to have been derived from the Arabs. Dr. Theophilus Hahn made some philological remarks upon this paper, and gave some illustrations of the Hottentot clicks. The President announced that this was the last meeting of the Ethnological Society as a distinct body, and read the terms of union whereby an amalgamation had been effected between the Ethnological and Anthropological Societies of London, under the common designation of "The Anthropological Institute of Great Britain and Ireland."

Edinburgh

Royal Physical Society, January 25.—Mr. C. W. Peach president, in the chair. The secretary exhibited a beautiful specimen of the snowy owl *Strix nyctea*, shot near Baltasound, Shetland, on the 24th of December. It was a female, and the remains of a dunin and a jack snipe were both found in its stomach. The facial disc and legs of the bird were pure white, the rest of the bird was whitish, barred all over with rich brown. Another specimen was seen in the same locality, probably the male bird. A curious specimen of a young rook was exhibited. It was of a uniform dull brown or ash colour, instead of the usual black colour, the bill being lightest coloured, and it was feathered down to the base of the bill.—Mr. G. F. Barbour, of Bonskeid, exhibited to the society a fine specimen of the spotted rail, *Crea porzana*. It was shot on the lands of Preston, near Linlithgow, in a bog on the hillside.—Note on the Nesting of the Kingfisher, *Alcedo ispida*, by Prof. Duns. The opening to the nest was twenty-two inches below the surface of the bank, and a little more than four feet above the water. The entrance to the nest was by a rounded passage, two inches wide at the front, increasing a little in size as it reached the oval chamber, or nest proper, and being only twenty-one inches long. The chamber was four inches broad, six long, and four high. After looking at the notices of the kingfisher's nest in the literature of ornithology, I find that the specimen before us sheds light on the following moot points:—1. The passage did not slope upwards, but was horizontal, the bottom being about half an inch below the bottom of the nest. "Instinct," says Montagu, "has taught them to have the entrance to their habitation ascending, by which means the filthy matter runs off." The matter referred to is the thin, watery fœces of the young birds, which soon becomes fetid. In this case the end indicated would be partially gained by the greater thickness of the small bones laid down in the passage than in the nest—the passage being thus brought to the level of the nest, and an imperfect kind of drainage supplied, by which, for a time, the watery fouling would be taken from the surface. 2. The hole was not the old hole of a water rat. 3. There were no traces of withered leaves or grass or feathers in the nest. The bottom was covered with the bones of minnows. The nest proper was perfectly dry, though the passage, especially at the edge of the nest, was wet and fetid. As the bones when disgorged must have been wet, it would appear that the pellets must have been scattered by the birds and left to dry before the eggs were dropped. 4. It is evident from this specimen that the bones of small fishes are as truly the lining of the nest as feathers are of the nests of many other birds.—"Note on the Plaice," *Platessa Vulgaris*, by Prof. Duns.—"Note on *Lithodes Maia*, fem.," by Prof. Duns. The specimen was taken at Elie, Fifeshire, in December last. It is a female. When received it was loaded with spawn, attached to branching tubes, situated beneath the abdominal plates; the size and arrangement of the abdominal plates, the presence and state of the ova, and the light shed by this specimen on the spawning time, of which Bell and others say they know nothing, deserve to be noted. *Lithodes Maia*, though occurring in the Firth, is no doubt one of our rarer crabs.—"Note on *Galathea strigosa*," by Prof. Duns, New College.—Mr. C. W. Peach exhibited *Antholithes* and its fruit (*Cardiocarpon*) with specimens of *Halonia*, *Flabellaria*, and other fossil plants, from the Coalfield near Falkirk.—C. W. Peach exhibited a large collection of fossil plants from the coal at the Cleuch No. 1 pit, and the brickwork near Falkirk, last summer. Amongst them was a series of *Antholithes Pitcairniæ*, some with its fruit, *Cardiocarpon*, attached, this being the first instance of the kind at present known. He stated that *Calamites*, associated with magnificent fronds of *Flabellaria Corassifolia*, were abundant. *Lepidodendron*, *Halonia*, *Ulodendron*, &c. &c., were much rarer; altogether, they showed that the flora of the coal period of Scotland was varied and of great beauty. He added that they were more interesting from the fact that several of them were generically and specifically identical with plants described in his "Acadian Geology," by Principal Dawson, found in the coalfields of Canada and America, even to the minute shells of *Spirorbis* still adhering to the fronds of *Flabellaria*.—"Notice of the Discovery of a new locality, near Edinburgh, of the Lower Carboniferous rocks, having fossils equivalent to the Burdiehouse and Wardie Series," by Mr. D. Grieve. Mr. Grieve read a notice of a new fossiliferous deposit discovered by him in certain shales and sandstones at Lochend, near Edinburgh, and which are situated on the east side of the loch. Mr. Grieve was led to make a search in this quarter from an indication given by Mr. Geikie, ten years ago, in his "Geology of the Neighbourhood of Edinburgh," that a continuity of the shales on the north side of the Calton Hill would likely be found between that place and Lochend, and which indication he had now verified. Mr. Grieve described the shales as belonging to the Lower Carboniferous formation, and as being equivalents of the sandstones and shales of Burdiehouse, Wardie, and Granton. He obtained *Calamites* of larger size and better marked than those found in the other localities stated as being abundant in the sandstone; *Lepidodendra*—a *Lepidophyllum*, *Sphenopterii*, &c. Of fishes he had obtained a beautiful specimen of the genus *Palæoniscus*, also scales, teeth, and spines, besides coprolites, which are abundant; also numerous specimens of a small crustacean, identical with *Cypris Scoto Burdigalense*, or of an allied species.

Glasgow

Geological Society, January 5.—Mr. E. A. Wunsch, V.P., in the chair. *Carboniferous Fossils*.—Mr. James Thomson read a paper on the occurrence of *Cœlacanthus lepturus* at Newarthill, and *Palæoniscus Wardii* at Possil. He briefly described the scales, fin-rays, and head-plates of *Cœlacanthus* which had been found in a detached form in the neighbouring coal measures, and which the examination of a nearly entire specimen from the Staffordshire coal-field had now enabled him to identify. It occurs in the upper members of the Carboniferous system in Scotland, in a shale overlying the ironstone of the Airdie coal-field. Both with regard to this and the other ichthyolite—the *Palæoniscus*—before them, he remarked that he had had these forms for years in his cabinet, unnamed; and it was only recently that *Palæoniscus Wardii* had been described, and named specifically after its discoverer in the Staffordshire coal-field, Mr. John Ward of Longtown. It is found in the Possil black-band ironstone, which is between four and five hundred fathoms below the position in which it occurs in Staffordshire, thus not only adding another form to the fauna of our Scottish coal-fields, but adding also to our knowledge of its range in time. The lower beds of the Ayrshire coal-field had also yielded some specimens of this fossil. Mr. Thomson then exhibited specimens of *Rhizodopsis sauroides*, *Amphycentrum granulosum*, and *Platysomus parvulus*, from the Staffordshire coal-field, observing that the scales of *Rhizodopsis* had been found in our Scottish coalbeds, but as yet no complete specimen of the fossil had thence been obtained. Mr. Thomson also exhibited specimens of *Oldhamia* from Bray Head, near Dublin. He described minutely the position of the beds in which these fossils are found, and complained that geological references are frequently so vague as to be of little real service to one going over the ground for himself. Two species of this fossil had been discovered, *O. antiqua* and *O. radiata*; and they were generally believed to have been zoophytes allied to the *Sertularia*. Their precise nature, however, is still matter of discussion. They possessed a special interest as being, with the exception now of *Eozoön Canadense*, the oldest distinct traces that had been found of life on the globe. Mr. Thomson further called attention to the wide unconformability presented by the Mountain Limestone near Dublin, resting, as it does, upon the Cambrian rocks on the north, and upon the granite on the south, side of the bay.

Philadelphia

Academy of Natural Sciences, October 11, 1870.—Dr. Ruschenberger, president, in the chair. Mr. Thomas Meehan said he had noticed a singular habit in the common "Stink bug" of gardens, *Reduvius novenarius*, Say, which might lead to some important physiological discoveries by those more closely devoted to entomological studies. Wondering what made some abrasion on the bark of a *Pinus cembra* on his grounds, he was attracted by a female insect of this species near it; and noticed that on the thigh of the middle leg the usual grey colour was of a polished black. Supposing that possibly the insect may have had something to do with the injury to the bark, through which the turpentine was oozing, he waited a few minutes to re-assure the insect—usually timid under observation—that there was no danger. It then went to work to take the turpentine with the heel of the tarsus of the fore leg, and place it on the thigh of the second leg. It took several dozen "heelsful," winding it round the gathering ball on the leg, as one would wind a ball of string. After it had collected together a ball of turpentine about the size of a pin's head, it gently wiped it off with the femora of the hind leg, and applied it to the anus, where it was very rapidly absorbed. It then walked very leisurely to the top of the nearest branch, when it flew away. This was in the end of September. He saw no more of these insects till a week afterwards, when he cut off a small branch on which was another female, and carried it to the pine tree, applying the branch to the stem so that the insect could walk on to it, without much suspicion of human agency in the matter. As soon as it got to the turpentine, it went through the same operation as the other one, taking two doses of it before it walked away; which it did leisurely, and with much apparent satisfaction. Up to this time he had not been able to find a male, so as to ascertain if it also had any similar use for turpentine.

Oct. 25.—"On the Stipules of Magnolia and Liriodendron," by Thomas Meehan. An examination of the stipules of *Magnolia* affords some highly interesting facts; most, or perhaps all of which are known to leading botanists, but which do not appear to be as generally known as they deserve to be; and which facts may have a more intimate bearing on many of the questions connected with the laws of development than is suspected. On the upper point of the scar next the leaf blade are two small articulation points, where the membranaceous stipules finally parted from the leaf. Examining a leaf before these stipules have fallen, the main veins forming the skeleton of the stipules are found connecting with these articuli, and spreading out, diverge downward toward the base of the leaf. I suppose no one of experience in living plants doubts the possibility of the adhesion of some parts and the separation of others, so as to make new parts or organs. If such is desired, I would refer to the *adhesion* of the carpellary leaves by their backs in the capsules of *Staphylia trifolia*; and for *separation* to the pinnate leaf often formed out of an entire blade in *Fraxinus excelsior, heterophylla*, and many other plants with entire leaves which often have pinnate ones amongst them. The author stated his opinion that the stipules of *Magnolia* are not formed like the stipules of most plants, which are perhaps leaf portions which have never been well developed, but rather are the tolerably well developed side pinnules of a trifoliate or deeply auricled leaf, which in an early stage had adnated with the petiole, and by their edges, and thus formed the stipular sheath we see. This ternate division of the leaf is a marked character in Ranunculaceæ, and with this exposition of a ternate type in Magnoliaceæ, its claim to a place in the Ranal alliance, strong as it always has been acknowledged to be, is still more strengthened. It is impossible to suppose that a so closely allied genus as *Liriodendron* should be founded on a different type from *Magnolia*. We shall see that only very slight causes, which we can well understand, have made some of the chief foliar distinctions, and the few which we cannot prove from actual facts, can be made almost certainties from parallel observations. The identity of type will in this way be manifest. There seems to be every evidence short of an actual witnessing of the fact, that the petiole in *Liriodendron* became adnate with the stem, and in this way the two lateral sections (stipules) were brought in contact with the stem with which they united. This would bring them nearer the sources of nutrition, and enable them to assume a more leaf-like and permanent character than if on the petiole. They become rather primary than secondary leaf organs, and this is just what we see them to be. Thus we may assume that *Magnolia* has typically a ternate leaf structure; that the stipules are the two lateral lobes which, by a peculiar process of adnation, became stipular sheaths after having been partially organised as leaf blade; and that *Liriodendron* differs from *Magnolia* only in possessing a greater power of adnation.

THURSDAY, FEBRUARY 9, 1871

THE POWER OF NUMERICAL DISCRIMINATION

IT is well known that the mind is unable through the eye to estimate any large number of objects without counting them successively. A small number, for instance three or four, it can certainly comprehend and count by an instantaneous and apparently single act of mental attention. The limits of this power have been the subject of speculation or experiment among psychologists, and Sir William Hamilton thus sums up almost the whole of what is known about it :—

"Supposing that the mind is not limited to the simultaneous consideration of a single object, a question arises, How many objects can it embrace at once? . . . . I find this problem stated and differently answered by different philosophers, and apparently without a knowledge of each other. By Charles Bonnet, the mind is allowed to have a distinct notion of six objects at once; by Abraham Tucker the number is limited to four; while Destutt Tracy again amplifies it to six. The opinion of the first and last of these philosophers appears to me correct. You can easily make the experiment for yourselves, but you must beware of grouping the objects into classes. If you throw a handful of marbles on the floor, you will find it difficult to view at once more than six, or seven at most, without confusion; but if you group them into twos, or threes, or fives, you can comprehend as many groups as you can units, because the mind considers these groups only as units; it views them as wholes, and throws their parts out of consideration. You may perform the experiment also by an act of imagination." (Lectures, vol. i. pp. 253-4)

This subject seemed to me worthy of more systematic investigation, and it is one of the very few points in psychology which can, as far as we yet see, be submitted to experiment. I have not found it possible to decide conclusively in the manner Hamilton suggests, whether 4 or 5 or 6 is the limit, nor do imaginative acts of experiment seem likely to advance exact knowledge. Probably the limit is not really a definite one, and it is almost sure to vary somewhat in different individuals.

I have investigated the power in my own case in the following manner. A round paper box $4\frac{1}{2}$ inches in diameter, lined with white paper, and with the edges cut down so as to stand only $\frac{1}{4}$ inch high, was placed in the middle of a black tray. A quantity of uniform black beans was then obtained, and a number of them being taken up casually were thrown towards the box so that a wholly uncertain number fell into it. At the very moment when the beans came to rest, their number was estimated without the least hesitation, and then recorded together with the real number obtained by deliberate counting. The whole value of the experiment turns upon the rapidity of the estimation, for if we can really count five or six by a single mental act, we ought to be able to do it unerringly at the first momentary glance.

Excluding a few trials which were consciously bad, and some in which the number of beans was more than 15, I made altogether 1,027 trials, and the following table contains the complete results :—

Estimated Numbers.	Actual Numbers.												
	3	4	5	6	7	8	9	10	11	12	13	14	15
3	23												
4		65											
5			102	7									
6			4	120	18								
7			1	20	113	30	2						
8					25	76	24	6	1				
9						28	76	37	11	1			
10						1	18	46	19	4			
11							2	16	26	17	7	2	
12								2	12	19	11	3	2
13										3	6	3	1
14										1	1	4	6
15											1	2	2
Totals . .	23	65	107	147	156	135	122	107	69	45	26	14	11

The above table gives the number of trials in which each real number was correctly or incorrectly guessed; thus in 120 cases 6 was correctly guessed; in 7 cases it was mistaken for 5, and in 20 for 7. So far as my trials went, there was absolute freedom from error in the numbers 3 and 4, as might have been expected; but I was surprised to find that several times I fell into error as regards 5, which was wrongly guessed in 5 per cent. of the cases. Abraham Tucker thus appears more correct as to my power than the other philosophers.

But in reality the question is not to be so surely decided by the trial of the few first numbers, as by endeavouring to obtain some general law pervading the whole series of trials. Calculating the average error of estimation in the case of each number, without regard to the direction of the error, we get the following numbers :—

3	4	5	6	7	8	9	10	11	12	13	14	15
0	0	·06	·18	·27	·44	·41	·65	·81	·73	1·08	1·21	1·27

These numbers vary pretty regularly in an apparently linear manner, except that in the case of the numbers 9 and 12, the result is too small. The error is simply proportional to the excess of the real number over $4\frac{1}{2}$, or obeys a law expressed in the formula (n being the real number)—

$$\text{error} = m \times (n - 4\tfrac{1}{2})$$

When we calculate the constant m for each number it comes as follows :—

5	6	7	8	9	10	11	12	13	14	15
·112	·122	·110	·127	·091	·117	·125	·098	·127	·128	·121

These numbers are sufficiently equal to enable us to take the average 0·116 as a good result, and the formula then becomes—

$$\text{error} = 0{\cdot}116 \times (n - 4\tfrac{1}{2})$$

or approximately—

$$\text{error} = \frac{n}{9} - \frac{1}{2}$$

This is a purely empirical law, the meaning or value of which I cannot undertake to explain. The most curious point is that it seems to confirm my previous conclusion that my own power of estimating the number *five* is not perfect. The limit of complete accuracy, if there were one, would be neither at 4 nor 5, but half-way between them; but this is a result as puzzling as one of the uninterpretable symbols in mathematics, just, for instance, like the factorial of a fractional number. But I give it for what it may be worth.

When we take into account the direction of the errors, the results are as follows:—

5	6	7	8	9	10	11	12	13	14	15
+ ·06	+ ·09	+ ·05	0·0	− ·05	− ·27	− ·46	− ·51	− ·85	− ·93	− 1·27

Thus there is a clear tendency to over-estimate small numbers and to under-estimate large ones. There is an evident inclination towards those medium numbers which most frequently recurred: how far this discredits the experiments I cannot undertake to say, but it is an instance of that inevitable bias in mental experiments against which it is impossible to take complete precautions.

My conclusion that the number five is beyond the limit of perfect discrimination, by some persons at least, is strongly supported by the principles of rhythm. All the kinds of time employed by musicians depend upon a division of the bar into two or three equal parts, or into multiples of these. Music has, indeed, been composed with the bar divided into five equal parts, but no musicians have yet been found capable of performing it (Rees' Cyclopædia, RHYTHM). Short runs, indeed, consisting of five or even seven equal notes, are not unfrequently employed by the best musicians, but it is to be doubted whether the ear can grasp them surely. I presume it is beyond doubt that 6, 8, 9, or more equal notes in a bar are always broken up by the hearer, if not by the performer, into periods of 2, 3, or 4. Quinary music, even if it could be executed, would be ill appreciated by the hearers, and, though all the powers of the human mind may be expected to progress in the course of ages, quinary rhythm belongs to the music of the distant future.

W. STANLEY JEVONS

BURMEISTER'S FAUNA ARGENTINA

FEW districts of the world are so rich in well-preserved remains of an extinct fauna of remarkable and interesting character as the neighbourhood of the city of Buenos Ayres. The immense alluvial plain of the Argentine Republic is the burial-place of the Megatherium, the Mylodon, the Glyptodon, the Macrauchenia, the Toxodon, and many other strange forms of ancient life, whose bones are ever and anon restored to light by the crumbling away of the soft banks of the great rivers which flow into the estuary of the Plata. So abundant, indeed, are they that, as remarked years ago by Darwin, any line whatever drawn across the Pampas would probably cross the skeleton of some extinct animal.

Collections of these fossils have at various times been sent to several European museums, and much information has been published upon the nature of the animals to which they belonged, but these observations have been generally made upon imperfect or fragmentary materials. The fortunate circumstance of the able and energetic German naturalist, Dr. Hermann Burmeister, formerly Professor of Zoology in the University of Halle, having taken up his residence at Buenos Ayres, and having been appointed Director of the Public Museum of that city, has been the occasion of a systematic and elaborate elucidation of the ancient fauna of this important district.

This has been brought about mainly by the publication of a richly illustrated serial quarto work, entitled "Anales del Museo Publico de Buenos Aires," the special object of which is to describe and figure the new or little-known objects preserved in that establishment. This work, which was commenced in 1864, appears at irregular intervals, but has already reached its sixth number, the first five of which constitute the first volume, the sixth, which is just published, being the commencement of a second volume. Dr. Burmeister is the sole author, and we have no hesitation in saying that it promises to be one of the most important contributions yet made to the knowledge of Mammalian zoology, for to his class is the publication mainly restricted. The parts already before us contain not only far more complete descriptions and detailed figures than have hitherto been given, of many of the extinct forms mentioned above, but it has also several admirable anatomical memoirs on rare or little-known living forms, especially of the Cetacea which occur in the estuary of the great river Plata, and in the adjoining part of the Atlantic Ocean, a field of research hitherto almost unexplored.

As this work, being written in the Spanish language, is not so well known in this country as it deserves to be, we propose to lay before our readers a summary of the contents of the volume already completed, from which they will be able to judge of the richness and variety of the material which has been at the author's disposal, and of the excellent use that has been made of it in his experienced hands.

After a history of the foundation and progress of the public museum of Buenos Ayres, and a general essay on palæontology, a detailed description is given of the skeleton of *Macrauchenia patachonica*. The first discovered remains of this very remarkable animal, which is about the size of a camel, were found by Mr. Darwin in 1834 at Port St. Julian on the Patagonian coast, and presented by him to the Museum of the Royal College of Surgeons of London, where they are now preserved. They were described by Professor Owen in the appendix to the "Voyage of the *Beagle*" (1840). Since that time but little addition was made to our knowledge of the species (although some bones of a smaller animal of the same genus, discovered by Mr. D. Forbes in Bolivian copper mines, have been described by Professor Huxley), until the lamented Bravard commenced the description, in a work to be entitled "Fauna fósil del Plata," of a comparatively perfect skeleton, which was contained in the museum of Buenos Ayres; but as he did not recognise its identity with Owen's Macrauchenia, he gave it the name of *Opisthorhinus falconeri*. The premature death of Bravard in the earthquake which destroyed the greater part of the town of Mendoza, prevented the publication of this work; but three of the plates, which had already been executed, containing figures of the skull with nearly complete dentition, and many of the vertebræ and limb bones, form the first three plates of the present work. To these, Dr. Burmeister has added another containing views of the pelvis and some more vertebræ, and an elaborate description of the whole of the known bones, finally concluding that the zoological position of the genus is among the imparidigitate or perissodactyle Ungulata, between the Horse and the Tapir.

After some remarks on the humming-birds described by Azara, a preliminary notice is next given on the different species of Glyptodon, or gigantic extinct Armadillo, in the museum. Three species are distinguished as well established, viz., *G. spinicaudus*, *G. clavipes*, and *G. tuberculatus*; a fourth, *G. pumilio*, smaller than the other, is founded on a portion of a lower jaw. Some general observations on the osteology of the genus are added.

The next portion of the work is called "Fauna Argentina, Part I., Fossil Mammals." It commences by a geological description of the fossiliferous region, and then follows a list of the fossil mammals of the "diluvian" deposits, with some remarks upon each. This list comprises, of Carnivora, *Machairodus neogæus*, of which the museum possesses a nearly complete skeleton discovered in 1844 near Lujan, about fifty miles west of Buenos Ayres. A short account of the osteological character of this interesting specimen is given, and a full and illustrated description is promised in one of the future numbers of the work. We have also *Felis longifrons*, *Canis protalopex*, *Canis avus*, *Mephitis primeva*, *Ursus bonærensis*. With regard to Marsupialia, it is singular that no remains of this group have hitherto been found in the diluvial deposits of the region in question, although, as is well known, they are not infrequent in the Brazilian caves explored by Lund. The list of fossil rodents includes *Myopotamus bonærensis*, *M. antiquus*, *Ctenomys bonærensis*, *Lagostomus angustidens*, and *Cavia breviplicata*. In the Edentata, the district is of course especially rich. Notices are given of *Megatherium americanum*, *Mylodon giganteus*, *M gracil s*, *M. robustus*, *M darwinii*, and a plate is devoted to the illustration of details of the osteology of these two genera, especially the hitherto little known sternum, sternal ribs, and hyoid bones. Then follow *Scelidotherium leptocephalum*, *S. cuvieri*, *Megalonyx meridionalis*, and *M. jeffersoni*. The genus *Glyptodon*, now divided into several sections, is represented by the following species: *G.* (*Panochthus*) *clavicaudatus*, *G.* (*P.*) *tuberculatus*, *G. clavipes*, *G.* (*Hoplophorus*) *asper*, *G.* (*H.*) *elongatus*, *G.* (*H.*) *lævis*, with several species but incompletely known. Numerous details are given of the osteology of these animals, with three plates of illustrations, one containing a view of a complete skeleton of *G. asper*. Under the head of Pachydermata, the teeth of two extinct species of horse, *E. curvidens* and *E. devillei* are described and figured, further notes are added on *Macrauchenia*, together with a complete view of the skeleton, and a restored outline of the animal with a slender elongated pendant proboscis, and some valuable details are given on the genus *Toxodon*, for the first knowledge of which, as in the case of *Macrauchenia*, we are indebted to Darwin's collection, described by Owen. Three species are now distinguished, viz., *T. burmeisteri*, *T. owenii*, and *T. darwinii*, appropriately commemorating the three distinguished naturalists by whose labours the history and affinities of this singular form have been made known. Three plates are devoted to the illustration of this genus. The list concludes with *Mastodon humboldtii*, to the osteology and dentition of which one plate is assigned.

The next and concluding section of the volume is entitled "Fauna Argentina, Part II., Mammifera pinnata." It is devoted to an account of the marine mammalia of the republic. Of the Pinniped Carnivora, *Otaria jubata* and *O. falklandica* are mentioned. The Manati is stated not to occur in the Argentine rivers. The Cetacea are represented by *Pontoporia blainvillii*, *Delphinus microps*, *D. obscurus*, *D. cymodoce*, *Lagenorhynchus cæruleo-albus*, *Orca magellanica*, *Phocæna spinipinnis*, *Globiocephalus grayii*, *Epiodon australe*, *Balænoptera bonæriensis*, *B. patachonica*, *Sibbaldius antarcticus*, and *Megaptera burmeisteri*.

A very detailed description is given of the external characters and anatomy of a newly discovered species of Ziphius, named by Dr. Burmeister *Epiodon australe*, which is not only valuable as being one of the most complete and fully illustrated accounts we possess of the structure of any Cetacean, but especially as the members of the particular group to which this one belongs are all exceedingly rare, or, at all events, have a remarkable habit of keeping out of the way of naturalists, and, consequently, are less known than almost any other section of the Mammalia. Descriptions, more or less detailed, are also given of the following new species:—*Globiocephalus grayii*, and *Orca magellanica*, both founded on characters of the skulls, which are figured. The former has much larger and thicker teeth than any other members of the genus to which it is referred. *Phocæna spinipinnis* is characterised not only by the numerous and regularly placed horny tubercles on the anterior edge of the dorsal fin (which are also frequently found, though in a more rudimentary condition, in the European porpoise) but also by the peculiar form of that fin, the anterior edge being concave, and by the conformation of the skull.

Not less valuable than the anatomical description of *Epiodon australe* is the article which concludes the work, which is a full and excellently illustrated account of the external characters and anatomy of a very singular and aberrant form of dolphin, hitherto but imperfectly known, called *Pontoporia blainvillii*. This animal is one of the smallest of the Cetacea, being but five or five and a-half feet long when adult. It inhabits the estuary of the river Plata and the adjoining parts of the ocean, but it is not truly fluviatile, like the *Mia* of the Amazon and the *Platanista* of the Ganges, to which two forms it presents some structural affinities.

We trust that the brief outline which we have given of the contents of the first volume of these "Anales" will be sufficient to show that it is a book indispensable to every good scientific library, and, in conclusion, we wish to express our cordial hope that the inhabitants and government of Buenos Ayres will continue zealously to carry on the creditable work they are doing for science in keeping up and augmenting their valuable museum, and that Dr. Burmeister will long continue to be the exponent of its treasures.

W. H. FLOWER

RECENT PETROGRAPHICAL LITERATURE

I.

Lehrbuch der Mineralien und Felsartenkunde. Von Dr. F. Senft. Jena. (London: Williams and Norgate.)

THE future historian of Geology who shall describe the rise and progress of the science in England, will find material for one of his most curious and interesting chapters in tracing out the causes which checked the growth, and finally all but extinguished the very existence of petrographical study in this country. While in all that relates to stratigraphical geology, we have kept well ahead of other nations, and have been quite abreast of them in palæontology, we have allowed petrography, or the study of rock-species, to fall into disuse. For half a century we have been content to make shift with vague, incorrect names invented in the infancy of the science; our progress in this respect since the early days of M'Culloch, Boué, and Jamieson, having been simply *nil*. More especially is this true of our nomenclature of igneous rocks. While we have unravelled the complicated stratigraphical structure and relations of these rocks with unrivalled labour and detail, we have left aside the questions touching their mineralogical ingredients and chemical composition, and their classification as mineral compounds. English petrography does not exist; what we have in its stead is an indefinite obsolete grouping of rocks patched up with occasional borrowings from the Continent. And yet, strange to say, it is in England that the most important step in modern petrography has originated. Sorby's application of the microscope to the study of rocks has opened a new era in the science, and our good friend Sorby himself is regarded as a kind of demi-god in the eyes of our German brethren of the hammer. But even his wand, though it has raised up a new army of zealous petrographers on the Continent, has, as yet, failed to quicken the dry bones of English petrography Mr. David Forbes is our *spes altera Romæ*. Our waiting eyes have been turned to his laboratory in York Place, Portman Square, for years past. His materials are vast, his enthusiasm great, and his intention fixed, to retrieve the honour of English petrography. May his shadow never be less until long after his wishes and our hopes are fully realised!

They manage things petrographical very differently in Germany. There the study of rocks is introduced into the curriculum of schools and universities. It is treated of in many excellent text-books. It is eagerly pursued by zealous investigators from Berlin to Vienna. The great paper of Mr. Sorby, published here thirteen years ago, has done much to quicken this research by showing that the older methods were in many respects untrustworthy. These methods were based primarily upon chemical analysis. But such analysis, while it reveals the ultimate chemical constitution of the rock, may not explain its mineralogical composition. The various stages of the metamorphism of the component minerals are thereby often lost sight of. Hence two rocks, having by analysis approximately the same chemical composition, may differ materially from each other in mineralogical composition. It is here that, as Sorby showed, the microscope comes in to our aid, and shows what the different mineral ingredients of the rock are, how far they have respectively undergone alteration, how they are built into each other so as to form the rock-mass, and under what conditions they may originally have been formed. This important addition to the methods of research has so powerfully affected petrography, that this branch of science must be regarded as at present in a transition state. Many of the groups of rocks in the nomenclature now in vogue in Germany will require reconsideration. More especially is revisal needed in those based upon subdivisions of the triclinic felspars. Petrographers are now coming to see that, in a vast number of cases, it is not possible to discriminate the particular species of felspar in a rock, further than as belonging to the othoclase or plagioclase division. In this separation the microscope becomes of essential importance.

A small pile of German petrographical literature has accumulated on our table, and we propose in this and a subsequent paper to notice the more important works. The first volume that comes to hand is another publication of that most voluminous writer, Dr. Ferdinand Senft, Professor of Natural Science, Eisenach. He seems to issue a goodly octavo every year, though possibly the past year's political events may have interrupted his labours for 1870. The present work is entitled "A Text-book of Mineralogy and Petrography," and contains some 700 pages. One would have thought that the Doctor had hardly left himself room for such a book as this, when we remember not only his former special treatises on the subject, but his text-book of "Forstlicher Naturkunde," one of the volumes of which is devoted to geognosy, soils, and chemistry. And yet the book differs materially from any of his former works, and, if we mistake not, is likely to be at least quite as useful. It is not designed to be an elaborate methodical text-book, but one in which the teacher and pupil will find all the material they require for a successful and methodical study of minerals and rocks, and also one which will prove sufficient for the student in his early inquiries, even without the help of a master. The author has had peculiar advantages for the compilation of such a book. In an interesting preface he tells us that for a quarter of a century he has been engaged in teaching these subjects to the two higher classes in a school, and he details the method of instruction which his experience has found to be successful. He had used the best mineralogical treatises as text-books in his classes, but had always found them too difficult for use in schools. Accordingly in 1860 he brought out a little "School Text-book of Mineralogy and Geognosy," which, having been out of print since 1866, he has remodelled and enlarged into the present work.

The general plan of the book is like that of the ordinary German text-books, only the first or mineralogical division occupies about five times more space than that devoted to petrography. It is of the latter that we have at present to speak. Retaining the usual grouping of crystalline and fragmental rocks, the writer gives a clear and succinct account of each subdivision and species. His plan for the specific details somewhat resembles that in his earlier work on the Classification of Rocks, but with some improvements. Under each species of rock, a clear but brief description of its leading features is given in large type, then follows an equally concise account of its varieties, transitions, mode of weathering, geological occurrence, and geographical distribution. The notes on the weathering of the different rocks, and the general remarks on that subject in the introductory part of the petrographical section, go some way to supply a want which every beginner soon discovers to exist in other manuals. The same commendation may be given to the descriptions of the various kinds of *débris* and soil formed by the decay of rocks.

As a school-book, the present volume seems likely to prove useful. The arrangement into short subdivisions, each clearly marked in the mode of printing, and treating each rock in the same method, will facilitate the progress of a class, and give precision to the inquiries of a beginner. Were there only any general taste for such pursuits in our own country, we might hope to see the book translated and adapted for use in our colleges and schools. At the same time, we are bound to notice what appears a very serious defect in the volume. The author has ignored recent microscopical research, and instead of giving that method a distinct and prominent place in his account of the investigation of rocks, he contents himself with the old "dry way" and "wet way" of analysis. In so doing, he tacitly confesses himself to be behind his time. His compilation, useful as it is, will, we hope, ere long be superseded by another, when petrography has had time to compose itself again into something like clearness and symmetry. In the mean time, the student who wishes to go more fully into the matter, will still find Zirkel's "Lehrbuch" his best guide, though even that valuable manual is fast getting out of date; owing to the great progress which the last few years have witnessed in this branch of geology. That progress has been largely shared in by Zirkel himself, as will be shown in a subsequent paper.

ARCH. GEIKIE

OUR BOOK SHELF

Der Zoologische Garten. Zeitschrift für Beobachtung, Pflege und Zucht der Thiere. Herausgegeben von Dr. F. C. Noll. XI. Jahrgang, 1870. (Frankfort a. M.) (London: Williams and Norgate.)

THE "Zoological Garden" is, as its name imports, a periodical especially devoted to all that is connected with the maintenance of animals in what are commonly called "Zoological Gardens." Having been founded some ten years ago by the Zoological Society of Frankfort-on-the-Main, it more especially relates to the affairs and condition of the small but well-arranged garden belonging to that Society, which is situated in the environs of that free and ancient city. It may appear somewhat surprising that a journal devoted to a subject of apparently so limited an extent can achieve sufficient circulation to command success. But the number of zoological gardens, aquarium houses, and similar establishments in Germany, has considerably increased of late years, and their institution in nearly all the principal cities of the Fatherland has been very favourably received, so that it is easy to understand that a considerable amount of popular interest in these subjects has been excited. Hamburg, Cologne, Dresden, Berlin, Hanover, and Munich, have all flourishing establishments of this description, and although the Zoological Garden founded some years ago in Vienna has come to an untimely end, yet in every part of what is now the new Empire of Germany the prospects of such institutions seem to be extremely favourable. But our "Zoological Garden" by no means entirely confines its attention to animals in captivity. It likewise contains many excellent articles relating to the habits of birds and beasts in a state of nature, so as to embrace many of the well-known attractions of a popular magazine of Natural History. Occasionally also more strictly scientific articles, such as that of Professor Pagenstecher on the Anatomy of the Cape Hunting Dog (*Lycaon pictus*) in the numbers for July and August last year, are given, so that the result is a zoological miscellany of a very various character. The woodcut illustrations are, it is true, perhaps not always in the highest style of art, but we have seen many inferior in English popular works of Natural History, and they have generally the merit of being tolerably correct. To such of our readers therefore as are growing weary of the "Zoologist," and cannot appreciate the learning of the "Annals," we recommend a trial of the "Zoological Garden," it being pre-supposed, of course, that they understand the language in which it is written (which in these days is a matter of course!). The subscription-price is very moderate, amounting only to about 8*s.* per annum for the twelve numbers, and the journal is regularly forwarded through the post to this country.

P. L. S.

The Marvels of the Heavens. By Camille Flammarion. From the French, by Mrs. Norman Lockyer. With 48 Illustrations. (London: R. Bentley, 1870.)

THE French certainly have the art, which we have not, of putting science in an attractive form to the popular mind—attractive, and yet not at the expense of scientific accuracy. Good service is, therefore, done by the translation into easy and graceful English of works like this by M. Flammarion. From the very commencement he carries the reader with him by his enthusiasm. Instead of starting with a bare statement of facts—that the Sun is the centre of the solar system, that it is so many hundred thousand miles in diameter, and has this, that, and the other planet revolving round it at such and such distances, he takes his reader out with him, as it were, to behold the heavens on a starry night; explains how it is that we see the sun only during a portion of the twenty-four hours; and speaks of the arrangement of the stars in clusters and nebulæ. Then he descends from the stars as a whole to a particular one, the Sun, and proceeds to describe in detail the solar system. And, throughout, the subject is treated with a graceful fancy and a wealth of illustration which make it very charming. Old Greek myths and fables of the astrologers, quotations from Byron and Lamartine, from Bryant and Victor Hugo, anecdotes of the value of astronomical knowledge, are brought in to point the moral and adorn the tale, and never appear to come amiss, or to be beside the mark. We must say a word about the illustrations, which are extremely good. We have never seen anything that so well recalls to our mind the appearance of the heavens through a powerful glass as Fig. 21, a part of the constellation of the Swan, as seen through the telescope; on the opposite page is placed, by way of contrast, the same seen by the naked eye. Author, translator, and artist have combined to produce a book which ought to be in the hands of every one who desires an introduction to "The Marvels of the Heavens." B.

Geology. By Prof. John Morris, F.G.S., and Prof. T. Rupert Jones, F.G.S. First series. Heads of Lectures on Geology and Mineralogy, in several courses from 1866 to 1870, at the Staff and Cadet Colleges, Sandhurst, by T. Rupert Jones, F.G.S. (London: Van Voorst, 1870.)

THIS book can hardly be called a Manual of Geology; it is rather the *avant-coureur* to the book which is to be written presently. It is a series of outlines for a course or courses of lectures, furnishing in a brief and concise form the heads or texts for any number of geological discourses which a Science teacher may be called upon to give: or the student may take it as his guide to the main lines and branches of geological study, along which he may have to pursue his readings in preparing himself, either alone or with the assistance of a "coach," to pass his "B.Sc.," or other examination at any one of the Universities. Now-a-days, when a man has to coach up so many different subjects in so short a time, it is obvious that, the more handy and concise a book is, the more useful will it be in helping to the desired end. One thing more seems to us to be needed in order to render this book of practical utility to the *uninitiated*; it is, to give, under each head, references to the authors (with chapter and verse) whom the student or teacher should consult, to gather more fully what is here only hinted at, often in but six words or less. To those who are already read up in Geology and Palæontology, the book is a most useful form of "Remembrancer," containing besides numberless facts — the key-notes to whole discourses on the earth and its past history.

H. W.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Cretaceous Period

In the number of NATURE for January 19 appeared a letter from Prof Wyville Thomson, in which he attempts to justify the opinion which has been concisely summed up in the words "we are still living in the Cretaceous epoch," a statement emphatically contested in the lately published "Students' Elements of Geology," by Sir Charles Lyell.

Prof. Thomson begins by supposing that the term Cretaceous epoch is considered by geologists as an undefined period of time which may very well be elastic enough to reach up to the present day; and, in this misapprehension of the exact meaning of geological terms, betrays the source of the whole misunderstanding. This accounts for an unnecessary digression about axes of elevation and raising the floor of the Atlantic to the surface; as if the possibility of part of that ocean having remained as such since the chalk period had ever been denied. It is known with certainty that a large area of Cretaceous sea existed where the Atlantic does not extend, but beyond our observations on dry land it is perfectly useless to speculate how far the present distribution of land and water coincides with that which obtained when *Belemnitella mucronata* was a living animal. Moreover the possibility of perfectly continuous and conformable series of deposits from the chalk period upwards being present somewhere at the bottom of the sea, has not received an atom of confirmation in the late deep-sea dredgings, and if true, would be no reason for laying aside a very serviceable classification based on other than purely stratigraphical considerations.

In speaking of organic remains, Prof. Thomson persists in misunderstanding the reasons on which the title "Cretaceous" has been founded, and so clearly defined in the controverted paragraph of the Student's Elements, p. 263. He cannot gainsay the fact that so many genera of Cephalopoda have completely disappeared, and, indeed, grants only a generic and specific resemblance between certain chalk fossils and recent deep-sea forms; which is obviously no adequate reason for the assumption that we now live in the Cretaceous epoch. It seems also to have been forgotten that our knowledge of this period is not confined to chalk strata, but is derived also from the examination of sand and clay formations in England, as well as those on the Continent and America, which are recognised as Cretaceous from their containing the same species of mollusca which characterise our chalk. Further, as the only organisms common to the Atlantic sand and the chalk are the Globigerina and other Bathybius, which are also common to the Indian and Pacific Oceans, any inferences drawn from their occurrence in the Atlantic are equally applicable to the two latter cases, and equally so to Eocene seas where Globigerinæ flourished along with Nummulites.

In fact the whole question is shortly this: calcareous mud has been dredged up from the bottom of the Atlantic, often from great depths. This mud resembles chalk so much as to leave no doubt but that the older deposit was produced under identically the same physical circumstances and organic conditions (as far as concern the matrix of Globigerinæ, Coccoliths, &c., but exclusive of all imbedded remains) as the newer formation. The outward resemblance of the two rocks, and the fact of the new deposit having been found so near where the old one accumulated, together with the recurrence of a form of Encrinite and a few Echinoderms, have imposed on Dr. Thomson, and led him to a conclusion which has no justification in facts. Had this eminent naturalist been an equally experienced geologist, he would have seen that, with the recurrence of outward conditions, it was but natural to expect a return of some old forms of life, as is the real state of the case. L. L.

A QUARTER of a century ago, when first I began to study geology, it appeared to me that a predominance was given to the more recent rocks, such as the Pleistocene, Miocene, Eocene, Cretaceous, and the like, to which they were not entitled, when ranked as periods alongside such great groups as the Carboniferous the Silurian, the Cambro-silurian, and the Cambrian. The more I have since daily learned confirmed me in this opinion, therefore it is with great interest that I have watched the discussion on the valuable suggestions of Drs. Thomson and Carpenter. Perhaps I may be allowed to join in the controversy, and to draw attention to some facts connected with the Carboniferous period, which seem to add weight to the arguments put forward by those gentlemen. Before proceeding further, I ought to state that in the Carboniferous period I include the so-called Old Red sandstone or Devonian period, on account of their being interpenetrated, dovetailed, and graduated one into the other in the S.W. of Ireland.

In the counties Limerick and Clare, well marked divisions occur in the Carboniferous period, of which the following is an epitome:—

11. Coal-bearing rocks.
10. Flag series.
9. Lower coal-measure shales.
8. Upper limestone.
7. Calp (shaly orgillaceous limestone, with shales and sometimes sandstones. Between the calp and the upper limestone a cherty zone may occur, but it is not constant).
6. Upper chert zone.
5. Amorphous limestone (Fenestrella beds).
4. Lower chert zone.
3. Lower shaly limestone.
2. Lower limestone shale.
1. Grit, &c. (Old Red sandstone, or Devonian period).

Certain fossils do range through all these divisions, while others will occur in all the similarly, or nearly similarly, circumstanced rocks; nevertheless, the major part of, if not all, these divisions have their groups of fossils. In some, a fossil first appears, in others it dies out, so that any one well acquainted with the rocks in the field can tell from the assembly of fossils to what division of the Carboniferous period the rock belongs.

The section of Limerick and Clare is only local, and will not be found in many places in Ireland. To the S.W. and S. in Cork and Kerry, some of the divisions die out, while others thicken, so that eventually in S.W. Cork and Kerry the limestones have entirely disappeared. To the N., N.E., and E. of Clare other changes take place. Moreover, they are not as gradual or regular as those to the S.W., and more especially if the rocks are followed towards the N.E. In north Galway the divisions in the limestone have disappeared, while interstratified with the limestone, in some place evidently high up (the representation of division No. 8) will be found sandstone, and conglomerates in aspect exactly similar to the so-called Old Red sandstone, and when fossiliferous containing similar fossils. Farther N.E. in the county Leitrim, the divisions are very similar to those in Clare, while still farther N.E. the different divisions become mixed, and in the coal-fields of Ulster will be found rocks similar to the coal measures, the Old Red sandstone, and the Carboniferous limestone, all interstratified one with another.

Neither are these rocks without breaks. In West Cork there is a continuous sequence either from the upper Silurian rocks, or rocks immediately above them to the coal measures; while in Kerry, there are in these rocks two well-marked breaks or unconformabilities, and in Limerick there may be another, as, at the only junction exposed, between the lower-coal-measure-shales and the upper-limestone, the limestone appears to have been denuded prior to the shales having been deposited. By the above it is shown that the condition under which the Carboniferous rocks were deposited, in the area that is now Ireland, are very varied in character, and if Great Britain were also included, other marked changes could be pointed out; as, for instance, in South Staffordshire, where there seem to have been subaërial accumulations going on during a great part of the Carboniferous period, as suggested by the vast thickness of the coal. If, in such a mere speck as Ireland, these great changes took place in the Carboniferous period, what must have been the vast changes on the whole earth's surface?

To me there appears to be a certain analogy between "the Carboniferous period" and the "Cretaceous period of Thomson and Carpenter." Both are great limestone periods, and both will have their coal beds. But what is more remarkable, Carpenter suggests that the geologist of future ages will separate the rocks forming in the "cold area" from the rocks forming in the "warm area," and put them in separate formations on account of the great difference in their mineral constituents and their assembly of fossils, while the greater number of the field geologists of the present age make two periods of the rocks of the Carboniferous period (viz., Carboniferous period and Devonian period), although the rocks of both groups are found to inter-penetrate one another, to dovetail into each other, and gradually to blend one into the other, both in lithological character and fossil contents.

Will any palæontologist take it on himself to say that there is a greater difference between the fauna of the Atlantic chalk and the chalk of England, than there is between the lower and upper divisions of the rocks of the Carboniferous period? Of course the Atlantic chalk is not to be represented only by the low forms found in the deep-sea soundings, as they do not represent its entire fauna. Years ago the late Mr. Salter pointed out at Glengariff, Co. Cork, that more fossils occur at changes of strata than elsewhere; such as the uppermost limits of a series of argillaceous or arenaceous beds, or at the top of a bed, if grits and shales alternate. This I have since found to be a good general rule, more especially when subordinate beds appear in a group. In Limerick, as well as other places in Ireland, masses of limestone may be without fossils, or, at least, conspicuous fossils; but if subordinate beds appear, such as the cherty zones, the aspect of affairs immediately changes, and, as a general rule, the rocks immediately subjacent to such changes are almost entirely made up of fossils and their *débris*. Similar changes are not only possible, but also most probable, in the Atlantic chalk. However, they are not likely to be proved in our day. But as in the limestone, so in the Atlantic chalk, in such places the mass of the fossils belonging to the latter ought to be found.

In considering such a question as the present, I would suggest that such fragile accumulations as those of the Kainozoic epoch ought to be considered of only minor importance; as most of them would be denuded away as the land sank, while those that chanced to remain would only form very subordinate strata. Moreover, Edward Forbes long since suggested that both from palæontological and petrological considerations, it might be better if the division between the Mesozoic and Kainozoic epochs were obliterated. Furthermore it has to be borne in mind that while in new strata very minute breaks can be detected; in old strata, like the Carboniferous period, it would be nearly impossible; and most of the great advocates for the minute division of the newer rock would not allow them in the old, as they explain everything they cannot understand by a "fault."

Connemara, Jan. 29 G. HENRY KINAHAN

Eozoön Canadense

THE organic nature of Eozoön Canadense may, I trust, be regarded as established conclusively by the evidence which has been adduced by Dr. Carpenter, Dr. Hunt, and myself, and I think I am safe in saying that it is accepted by all or nearly all those best qualified to judge. Since, however, the doubts expressed by your correspondent, Mr. Reade, may be shared by many who have not had full opportunity to satisfy themselves on the subject, I think it may be useful once more to direct attention to the facts serving to answer the objections which he has stated, and which, on more full consideration of the questions involved, I trust he may abandon.

Your correspondent objects: First, That the supposed Liassic serpentine or ophiolite of Skye shows structures similar to those of Eozoön. In answer to this it is not necessary to have recourse to the supposition that creatures similar to Eozoön have continued to exist up to the Liassic age, since, as Dr. Hunt has shown,* there is reason to doubt the accuracy of the observations which refer this rock to the Lias; and, further, Profs. King and Rowney, in a recent paper on Eozoön in the Proceedings of the Royal Irish Academy,† have figured this supposed Eozoön, and have thus shown that the portions of it which they consider similar in structure to the Canadian specimens do not possess such structure. I would not, in any Canadian specimen, accept such appearances as those represented in their figure as the Eozoön. This objection is therefore wholly irrelevant.

He objects: Secondly, That Eozoön occurs only in metamorphic rocks, and usually mineralised by serpentine. To this I answer: (1.) It unfortunately happens that Eozoön is a fossil of the Laurentian period, and that the rocks of this age are in a more or less metamorphic state in every part of the world where they are known. When we shall have found unaltered Laurentian rocks it will be time to inquire if this fossil occurs in them, and in what state of preservation. (2.) I have elsewhere shown that the chambers and canals of Eozoön are filled not only with serpentine but with other mineral substances, as Loganite, Pyroxene, and Calcite. There is thus, as Sir William Logan affirmed previous to the discovery of the minute microscopic structure, no connection between the forms of the supposed organism, and the mineral substances in connection with which they appear.

In the third place, in order to be enabled to make the assertion above referred to, your correspondent "disposes of" the Tudor specimen, which, as compared with the others examined, occurs in a comparatively unaltered sediment. With regard to this specimen, I affirm, and the published figures show: (1) that it presents the characteristic features of Eozoön, more especially resembling the specimens from the Calumet and from Perth; (2) that other specimens found in the same locality confirm its determination as Eozoön; (3) that the matrix containing the Tudor specimens is a coarse limestone not more metamorphic than many Silurian beds holding fossils. I have, however, to state that the recent explorations of Mr. Vennor, of the Geological Survey, seem to show that the beds which afforded the Tudor specimen, though unconformably underlying the Lower Silurian, overlie the highly metamorphic Lower Laurentian of the district, and, therefore, instead of being, as heretofore supposed, comparatively unaltered Lower Laurentian, they may prove to be even as late in age as the Cambrian. It is in these rocks that the worm-burrows which I observed some time ago occur.*

Fourthly, he alleges imitative forms which Profs. King and Rowney consider to be "identical with the thing itself." Now, imitative forms are not unknown to palæontologists. I have seen rill-marks figured as fossil leaves, and trails of worms and other mere markings, as fossil plants of various kinds; and many dendritic crystallisations are wonderfully like mosses and algæ. I have on my table at this moment a curious group of rounded concretions of black oxide of manganese in a coal-formation sandstone, which I received a few days ago from a very judicious collector, who believed that it was an undescribed fruit. But such things do not invalidate the evidence of real fossils. It is to be observed, however, that while it is extremely easy to assert that such imitative forms are identical with fossils, and even to make this appear plausible in descriptions and drawings, careful examination of actual specimens, with attention to chemical conditions and modes of occurrence, may be necessary in order to draw the proper lines of distinction. In the case of Eozoön, the imitative form has neither been shown to unite the general arrangement, microscopic structure, and mode of occurrence of the fossil, nor perfectly to resemble it in any one of these respects.† In so far as my own comparisons have extended, I am prepared to demonstrate the difference between all such crystalline, dendritic, and concretionary forms, and the Canadian Eozoön.

Your correspondent merely confines himself to general assertions and to starting difficulties. His authorities, Profs. King and Rowney, in the paper above referred to, have ventured on the more dangerous ground of constructive criticism, and have endeavoured to explain the way in which they suppose Eozoön to have been produced. In doing so they have been obliged to resort to an extravagant and complex theory of pseudomorphism, which I fancy most of the palæontologists will throw down in despair of comprehending it, and which I am sure any competent mineralogist or chemical geologist who studies it, will reject as much more trying to his faith than anything required to explain the occurrence and preservation of Eozoön as a fossil.

Lastly, your correspondent desires further investigations with reference to the questions involved in the organic character of Eozoön. It may satisfy him to be informed that Dr. Hunt and I have just sent to Dublin a reply to the objections of Profs. King and Rowney, in their paper above referred to; and that I have for some time been pursuing investigations of Primordial and Silurian fossils akin to Eozoön either in structure or mode of preservation. When these investigations are completed, I hope to show that Eozoön has several foraminiferal successors in the older palæozoic rocks of Canada, and that fossils of various kinds occur in those rocks infiltrated with mineral matters in a manner not dissimilar from that observed in the Laurentian Eozoön. Natural Science at Cambridge

"M.A." will best satisfy himself as to the grounds for the sentence which appeared in NATURE for January 12, to which he demurs, respecting the willingness in Cambridge to award fellowships for merit in Natural Science, by making inquiries of the tutors of the several colleges. This I trust he will do, and if he takes the opportunity of impressing upon them the advantage of following the example set by Trinity of absolutely offering a fellowship or fellowships as the reward of great proficiency in Natural Science, he will be doing a great service, for that is unquestionably an important desideratum. At the same time, I would ask him to take the trouble to ascertain whether there have recently been in Cambridge any persons of great proficiency in Natural Science to whom fellowships have not been awarded. A close and fair examination of the matter will, if I mistake not, prove to him that the colleges have not been backward in this way in rewarding real merit in Natural Science; that there is in some colleges not only a willingness but an anxiety to do this; and that the arena is opening for Natural Science to enter the lists against Classics and Mathematics, with the prospect of a fair adjudication of fellowship prizes. "M.A." will do a further great service if he can turn his wide acquaintance with the members of various colleges to account by inducing the colleges to offer more Scholarships for proficiency in Natural Science, instead of limiting them so much, as is at present done, to students who have not commenced a University career. The stimulus thus afforded to the study of Natural Science by undergraduates would have the effect of producing a greater number of candidates deserving fellowships, and the more frequent award of fellowships to them.

THE WRITER OF THE ARTICLE IN QUESTION

Feb. 4

Prismatic Structure in Ice

DURING the late frost and subsequent thaw, I have watched the ice as far as was in my power to see whether its demeanour bore out Mr. Langton's explanation of the prismatic structure (NATURE, vol. iii. p. 105) in reply to my communication (Id. vol i. p. 481). At the time when I received his letter, I felt unable to accept the compromise which he proposed, and the result of these last investigations has been to confirm my previous opinion. Let me, however, first explain away a slight misconception into which I have led him. In using the words "*severe* frost," I spoke as an Englishman, and used the epithet relatively, without thinking how it might be understood by one accustomed to a colder climate. All I meant was a frost severe enough to form ice more than an inch or so thick.

I will first give you the result of my observations, and then proceed to answer the questions which Mr. Langton proposes.

On December 26, while skating for some hours on a pool in Hagley Park, Rugeley, I examined the ice carefully, but could detect no trace of the prismatic structure. The air bubbles, generally more abundant towards the lower side of the ice, were irregularly dispersed, and not in any way arranged in vertical lines, and the ice had its usual fracture. On Tuesday, January 3, and the following day, I again skated on the same pool, and could not ascertain that any noteworthy change had taken place during my absence in such parts of the ice as were free from snow. Then came a thaw, on the first day of which I visited the pool; the sloppy state of the surface, owing to the melted snow, made examination difficult; but on breaking the ice, I detected occasional traces of the prismatic structure. On returning in the afternoon of January 7, I found that a slight frost during the morning had been sufficient to make the ice safe, though the surface was still wet in places. Now, however, there was a marked change in its appearance; in many spots the delicate surface-reticulation caused by the prismatic structure could be detected; small air-bubbles, as it seemed to me, were more numerous, and very many of them were arranged in vertical lines, which when produced, met the angles of the surface-polygons. In a few cases they were not in vertical but in sloping lines; here it was evident that from some accidental cause, the sides of the prisms had not been at right angles to the surface of the ice; this, however, was rare. Everything that I saw convinced me that the lines of bubbles as a rule were the consequence of the prismatic structure, not the cause of it. The quantity of snow and sleet that subsequently fell made it impossible again to examine the ice satisfactorily before I left the neighbourhood, though I visited the spot more than once. Yesterday and to-day I have been examining the ice on a pond in the Botanic Garden here, which is gradually melting away. It exhibits almost everywhere the delicate prismatic structure which I described last year. On withdrawing fragment after fragment, one to two inches thick, from different parts of the pond, I found the surface covered with a most delicate reticulation, and the edges crenulated, as though the whole were a model of a sheet of columnar basalt. The distance between opposite angles of the surface-polygons was generally from $\frac{1}{8}$ to $\frac{1}{4}$ of an inch. Here and there the ice-slab was partially or wholly perforated, the surface-water having penetrated at the junction of a set of joints, and dissolved away more or less of the adjacent columns; in not a few cases these apertures were polygonal, whole columns having perished. There were, of course, many air-bubbles; but I could see nothing to lead me to suppose that they had caused the structure; thousands more would have been required than I could discover, for in many places where the structure was very perfectly exhibited there was hardly a bubble to be seen.

With regard to the first of Mr. Langton's questions, "Does ice contract on approaching 32° F.?" Jamin ("Cours de Physique," vol. ii. p. 108) states that it does; and though he does not mention either the amount of contraction or the point of minimum density, the former, from his illustrative diagram, appears not inconsiderable. (2.) "Do air-bubbles form from the first in vertical lines?" I should say not, as a rule. (3.) "Is there any indication, as the winter advances, of a re-arrangement of the bubbles, as that they run into each other, and get more and more ranged in vertical lines?" None that I can discover. (4.) "Is there any indication in the earlier stages of the ice that after a night's hard frost the cracks seen on its surface spread through its substance?" I have not observed any. The fifth question I have not at present the means of answering; but that does not materially affect the point in debate.

I may add that while visiting the Schafloch Glacière, during the past summer, I noticed that, near the entrance of the cave, the ice everywhere showed prismatic structure, but that near the extremity, where the temperature was at the time about 30° F., there was little, if any trace of it.

One word in conclusion to this long letter, on a point of practical importance. I am now convinced that this minute prismatic structure is the rule rather than the exception in a thaw, though it has hitherto been overlooked; and that it is the chief cause of the "rottenness" in ice. When it has been set up, a slab of ice 5 or 6 inches square, and full one inch thick, can be broken across as easily as if it were a cake of bread; and slabs little larger will snap in two when dropped flat on level turf from a height of less than eighteen inches. Almost every thaw brings its melancholy tale of persons drowned while skating on ice which, though thick, proves on trial to be "rotten." I have no doubt that in every one of these cases it had become prismatic. Therefore all who are about to venture on the ice, when a thaw is setting in, should look carefully for the signs of this structure, and if it is present keep their distance.

St. John's College, Cambridge, Jan. 17

Coming Home from Sicily

THE Eclipse Expedition has gone forth and returned, having on the whole been most successful in its observations. But never, perhaps, was science pursued under greater difficulties. The hot haste in which all the necessary preparations and arrangements had to be made and perfected before departure is already well-known; the combination of circumstances which impeded our locomotion on the outward journey to Sicily; the slight mishap on the Brenner, and the unfortunate loss of the beautiful *Psyche* have been noised abroad, but the return journey was not accomplished without mishaps, although nothing has been said about them. The stars in their courses fought against Sisera not more relentlessly than did the elements against us.

The Eclipse over, with all possible speed we packed up our instruments and started for Naples, being anxious to hasten homewards. We reached Messina on Monday, 26th December, with the full intention of sailing immediately. But a sirocco prevailed, which snapped the telegraph cable to Naples, and prevented our finding out anything about the movements of the steamer. Daily we expected the arrival of one from some quarter or other which might take us back, but we hoped against hope that each day would be our last in Sicily. It was not until late on Friday afternoon, Dec. 30th, that our hopes were answered, and we weighed anchor.

In due time we reached Naples (after a rough passage), and there our party divided. Between Naples and Rome the communication was open, but, on arriving at Rome, we found very evident traces of the recent inundations, which are said to express the indignation of Providence or the delight of Father Tiber at the downfall of the Pope's temporal power. The regular route from Rome to Florence *viâ* Foligno and Perugia, was no longer available, as the flood had carried away most of the bridges on the railway, so we were compelled to take the other and very circuitous route *viâ* Civita Vecchia, Pisa, and Empoli. From Florence, after a delay of two days, during which large quantities of snow fell, we made an attempt to reach Bologna on January 9th, but our ill-luck still followed us, and we had to return whence we had come.

By the advice of some Italian friends, we decided to wait a few days at Florence before making a second attempt to cross the Apennines. Luckily we succeeded the next time in crossing the mountains and leaving Lombardy without any great inconvenience, for by this time the four feet of snow which had covered the country everywhere had been cleared from the rails. We experienced no further difficulty until we arrived at Brenner, where, after remonstrances on our part, we were turned out in a heavy snowstorm to find our way as best we could to the nearest hotel. The next morning we found that the cause of the delay was an avalanche, which, descending a very short time before our train came up, and carrying with it in its downward course trees and rocks, had effectually blocked up the line of rails. Vague rumours reached the hotel that no trains would pass for a week, that two battalions of Austrian soldiers were cutting a way through the snow, and that the avalanche was 200 yards in length, 80 feet in height, and extending across the gorge from side to side. We had no means of verifying these statements, as the telegraph wires were broken, and the officials were evidently as much in the dark as ourselves. Twenty-four hours after us the train bearing the Indian mails from Brindisi came up to the same spot, the passengers were treated as we had been, and ordered to turn out at midnight in happy ignorance of the cause of the delay. The mails were, however, sent up as near as possible to the obstruction, and thence carried over the tops of the mountains for a distance of eight miles, to a train which was waiting on the further side. The cold was intense at Brenner, and the depth of the snow confined us to the hotel. The weather, however, was only such as might be expected on the Alps, but we had good reason to fear from famine, as each successive train brought up regularly from Verona its freight of passengers, and discharged them all at Brenner, until the two hotels were full and overflowing. On the evening of the third day, as we sat at dinner, tidings came that the line was once more clear, and that a train would probably start that evening for Munich; so, thankful to quit the dull monotony of Brenner, we left by the night train, and after a delay of two days in passing through the disturbed parts of Germany, we arrived safely in England, having spent eight days *en route* from Florence.

W. A. HARRIS

St. Michael's Mount

IN the last number of NATURE there appears a letter from Mr. R. A. Peacock, of Jersey, in which he attempts to prove that St. Michael's Mount, in Cornwall, was insulated in the eleventh century. To do this, he quotes the passage from Domesday relating to the lands held by the church of St. Michael, which he translates—"Keiwal holds the church of St. Michael," &c. Now this land, Mr. Peacock says, was 240 acres, but the area of the Mount is now only 30 acres, so that there are 210 acres missing, therefore it could not at that time have been an island, because, in the eleventh century, it contained at least eight times as much land as it does at present.

Unfortunately for this theory, the passage which Mr. Peacock translates "Keiwal holds the church of St. Michael" is really "The church of St. Michael holds Treiwal, or Treuthal," as it is called on p. 11, which is a manor in the parish of St. Hillary, Cornwall.

H. MICHELL WHITLEY

Penarth, Truro, Feb. 6

The Zodiacal Light

IN NATURE for January 26, in the course of an interesting account of the Augusta Eclipse Expedition, by Prof. W. G. Adams, of King's College, there is a short allusion to the Zodiacal Light, which can hardly fail to be looked on by many as being, both on account of the author and the occasion, authoritative as well as important and instructive:—"At about 6^h 30^m on Monday evening (runs the article in question) we saw a brilliant display of the zodiacal light, consisting of brilliant pink streamers, stretching perpendicularly to the horizon, the planet Jupiter being just on the most brilliant streamers. Towards the north and round the horizon there were also streamers," &c.

Until assured by the author that the word "zodiacal" is not a misprint from something else, it is hardly worth while for me to point out in detail that the above description mentions almost everything which does *not* belong to the true zodiacal light, and nothing which does belong to or characterise it as hitherto known amongst astronomers.

C. PIAZZI SMYTH

The Reign of Law

THE following is an extract from a letter I lately received from a friend of mine who is on the Geological Survey of India:—

"The Duke of Argyll and his Council have determined that the leave-rules, which are good enough for the natives, are good enough for us, although they are not sufficiently good for educated Europeans, such as the Staff Corps and Civil Service, and this they have resolved on, in spite of the Indian Government. If we could only get fair leave and pension rules, the same as men of the same rank and education receive in the other services, I do not think I should be tempted to give up field-work."

May I be allowed to inquire whether this is a new illustration of "The Reign of Law?"

TANTALUS

Misadventures in Conchology

MY experience seems to me curious; is it unique? I don't complain, I simply inquire.

1. As channel of communication for a foreign friend, I sent copies of his valuable conchological work to three public libraries in Great Britain. I know they were received. They have never been acknowledged.

2. I sent a complete set of shells, of a specially interesting field, to a foreign collection; they were delivered by a friend. They have never been acknowledged.

3. I sent (at his request) to a man of science a number of the rarer shells of a district. He acknowledged them through his clerk.

4. To a dealer at his urgent request and offer of exchanges, I sent a quantity (some hundreds) of shells. He sent me in return less than half what he had promised, selected from my list at his fancy.

5. To a scientific man in America, at his earnest request and offer of exchange, I sent a set of the shells of a district. No answer whatever.

6. I sent a unique specimen of a shell to a foreign conchologist for examination. I have never heard more of it.

7. At the earnest request of a dealer offering exchange, my brother sent a great number of Scotch glacial shells. His letter of request for desiderata was returned unopened.

8. A friend near me has more than once sent shells to German collectors, but has the same sad tale of packets sent, and no promised returns made.

Are these experiences exceptional, or is conchology fatal to conscience, or are *all* men liars?

VALLE

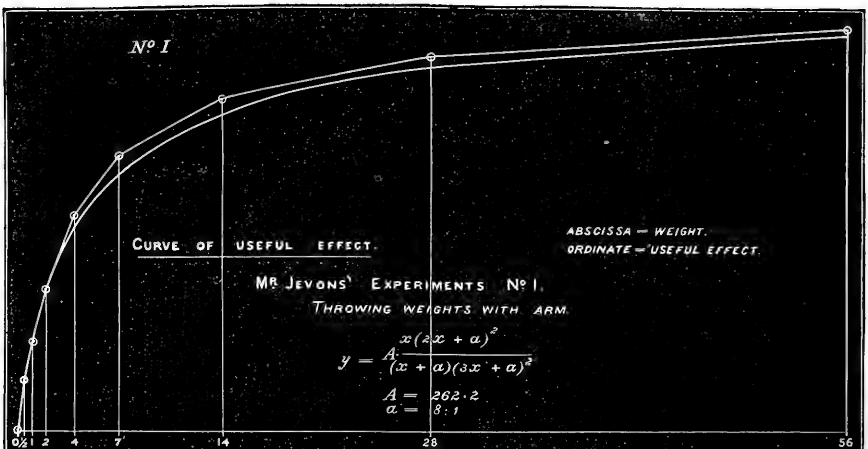
ON THE NATURAL LAWS OF MUSCULAR EXERTION

II.

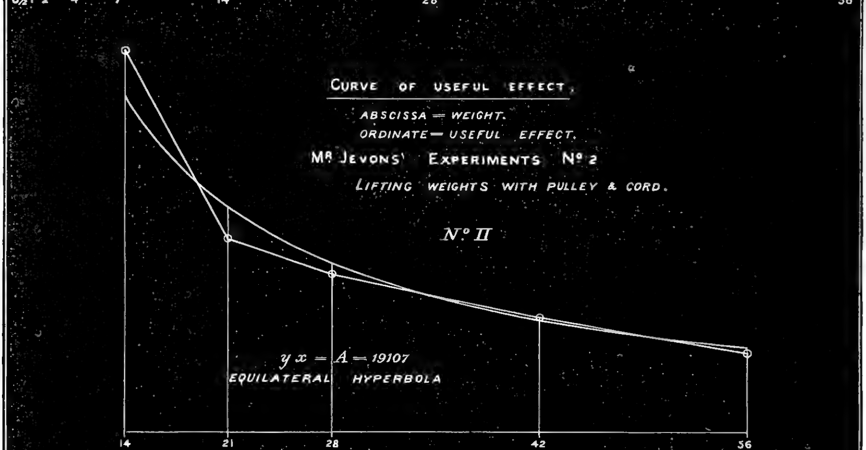
HAVING shown* that Mr. Jevons' first and third sets of experiments illustrate laws 1 and 2 of muscular action, it remains for me to apply the same laws to his second set of experiments, and to show that they also illustrate these laws.

Before doing so, a few words may be said on the subject of the *maximum* of useful effect. I have shown, from theory, that a *maximum* of useful effect is obtained in holding out weights horizontally in the hand, by using a weight which is 73 per cent. of the weight of the arm

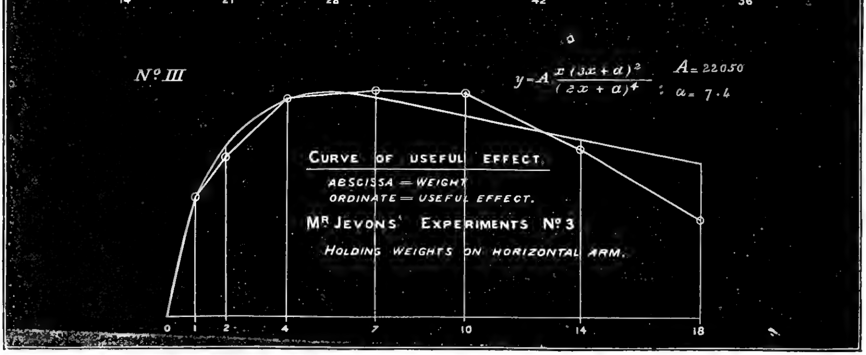
* See NATURE, vol. ii. p. 324.



Nº I
Curve of useful effect.
Abscissa = weight.
Ordinate = useful effect.
Mr Jevons' Experiments Nº 1.
Throwing weights with arm.
$y = A\dfrac{x(2x+a)^2}{(x+a)(3x+a)^2}$
$A = 262{\cdot}2$
$a = 8{:}1$
0 ½ 1 2 4 7 14 28 56



Curve of useful effect.
Abscissa = weight.
Ordinate = useful effect.
Mr Jevons' Experiments Nº 2
Lifting weights with pulley & cord.
Nº II
$yx = A = 19107$
Equilateral hyperbola
14 21 28 42 56



Nº III
$y = A\dfrac{x(3x+a)^2}{(2x+a)^4}$; $A = 22050$; $a = 7{\cdot}4$
Curve of useful effect.
Abscissa = weight
Ordinate = useful effect.
Mr Jevons' Experiments Nº 3
Holding weights on horizontal arm.
0 1 2 4 7 10 14 18

itself, and this result agrees with the experiments. In throwing weights with the arm Mr. Jevons found that there was no true maximum of useful effect, and that it increases with the weight used.

It can be shown from the equations used by me, which are deduced from Law 1, that this result might have been predicted from theory.

The useful effect is proportional to

$$w \times R,$$

or to

$$w \times V^2,$$

which, by equation (2), becomes

$$w \times \frac{a^2}{l^2} v^2;$$

this expression varies as the following, by equation (3)

$$w \times \frac{(2w + x)^2}{(3w + x)^2} v^2;$$

and since, by equation (1) or Law 1, v^2 varies inversely as $w + x$; we obtain finally

$$\text{useful effect} = \frac{Aw(2w + x)^2}{(w + x)(3w + x)^2} \tag{13}$$

The condition necessary to make this expression a maximum is

$$w(2w + x)(9w + 7x) = (w + x)(3w + x)(6w + x);$$

which reduces to the quadratic equation

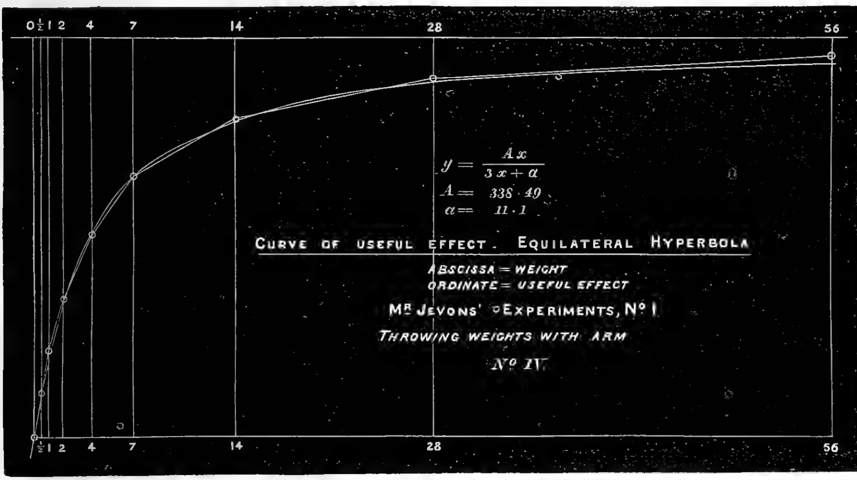
$$4w^2 + 3xw + x^2 = 0 \tag{14}$$

This equation has imaginary roots, viz.:

$$w = x\left(\frac{-3 \pm \sqrt{-7}}{8}\right)$$

Hence there exists no real value for the weight thrown which will make the *useful effect* a maximum.

Mr. Jevons' second set of experiments consisted in raising and lowering various weights by a pulley and cord, through the convenient range of the arm, and noting the number of times the weights were raised, the rapidity of the motion being maintained constant.



The results of these experiments are

Weight.	No. of times raised.
56 lbs.	5·7
42 „	11·9
28 „	23·0
21 „	37·6
14 „	110·0

It is easy to see, on theoretical grounds, that the weight (x) of the arm will disappear from the equations that represent the work done in these experiments; for in raising the weights the work done is proportional to

$$(w - x)\, n,$$

and in lowering the weights the work done is

$$x\, n.$$

These two, added together, give for the total

$$\text{Work done} = w\, n.$$

I have verified this anticipation of theory by introducing x into the *ten* equations furnished by the *five* simultaneous values of w and n, and I find that the mean value of x turns out to be

$$x = 0{\cdot}18 \text{lb.},$$

a value which, if the experiments were absolutely accurate, ought to become zero.

The rate of work is proportional to w, and multiplying this by the work done, in accordance with Law 2, we find

$$w^2 n = A \tag{15}$$

This equation gives the following values of A, corresponding to the five simultaneous values of w and n:

A	w
17875	56 lbs.
20992	42 „
18074	28 „
16582	21 „
21560	14 „

The mean of these values is

$$A = 19017.$$

Solving equation (15) for n, we find

$$n = \frac{A}{w^2}. \tag{16}$$

Substituting for A and w, in this equation, we find the following comparison of theory and observation:

w	n (observed).	n (calculated).	Difference.
56 lbs.	5·7	6·0	$-$ 0·3 ($\frac{1}{19}$)
42 „	11·9	10·8	$+$ 1·1 ($\frac{1}{11}$)
28 „	23·0	24·2	$-$ 1·2 ($\frac{1}{19}$)
21 „	37·4	43·1	$-$ 5·5 ($\frac{1}{7}$)
14 „	110·0	97·0	$+$13·0 ($\frac{1}{9}$)

This table is satisfactory, as the differences are less than possible errors of observation.

The *useful* effect admits of no maximum in these experiments; for it is represented by wn, and

$$w \times wn = A;$$

therefore—

$$wn = \frac{A}{w}; \qquad (17)$$

which represents an equilateral hyperbola; wn becoming infinite when the weight is zero.

The agreement between Laws 1 and 2 and Mr. Jevons' experiments, may be best shown by means of the accompanying tables and diagrams, which represent the curves of useful effect, calculated from Laws 1 and 2.

First Set of Experiments.

Throwing weights.—It follows from equation (5) that the useful effect

$$= wR = A\frac{w\,(2\,w + x)^2}{(w + x)\,(3\,w + x)^2} \qquad (18)$$

Substituting in this equation, the values

$$A = 262·2$$
$$x = 8·1$$

we obtain the following table:—

Useful Effect No. 1.

w	wR (observed).	wR (calculated).
0	0	0
$\frac{1}{2}$	13·2	13·6
1	23·6	23·8
2	39·2	38·2
4	58·6	55·6
7	74·3	70·1
14	90·4	86·4
28	101·6	98·5
56	108·1	106·5

In the accompanying curve No. 1, the abscissa is the weight, and the ordinate the useful effect; and the centres of the small circles represent the actual observations.

Second Set of Experiments.

Lifting weight with pulley and cord.—In these experiments the useful effect wn may be at once calculated from equation (17), from which the following comparison is made, and Diagram No. 2 constructed.

Substituting for A, its value 19,017, we find—

Useful Effect No. 2

w	wn (observed).	wn (calculated).
14 lbs.	1554	1358
21 „	790	905
28 „	644	679
42 „	500	453
56 „	319	340

The curve represented in Diagram 2 is a portion of an equilateral hyperbola, whose abscissa is the weight, and its ordinate the useful effect.

Third Set of Experiments.

Holding weights on hand extended horizontally.—The useful effect in these experiments may be calculated from equation (11).

$$\text{Useful effect} = wt = A\,\frac{w\,(3w + x)^2}{(2w + x)^4}. \qquad (11)$$

Substituting for A and x their values

$$A = 22050$$
$$x = 7·4$$

we obtain the following comparison, and construct Diagram No. 3.

Useful Effect No. 3.

w	wt (observed).	wt (calculated).
0	0	0
1	321	306
2	438	468
4	592	590
7	612	594
10	603	547
14	455	479
18	266	421

In Diagram No. 3, as before, the abscissa of the curve represents the weight, and the ordinate denotes the useful effect.

The equations of the three curves which represent the useful effect in Mr. Jevons' three sets of experiments, when expressed in Cartesian co-ordinates, are as follows:—

$$y = A.\frac{x\,(2x + a)^2}{(x + a)\,(3x + a)^2} \qquad \text{No. 1}$$

$$y\,x = A \qquad \text{No. 2}$$

$$y = A\,\frac{x\,(3x + a)^2}{(2x + a)^4} \qquad \text{No. 3}$$

It will be interesting, in conclusion, to explain why the simpler empirical formula, used by Mr. Jevons, coincides so nearly with the more complex formula deduced from theory.

According to Mr. Jevons' empirical formula, the useful work done in throwing weights is

$$\frac{B\,w}{2w + x}$$

where B = 231·4; and, according to my formula, deduced from theory, the useful work is

$$\frac{Aw\,(2w + x)^2}{(w + x)\,(3w + x)^2}$$

where A = 262·2.

These two expressions, algebraically considered, can never become identical, but may become nearly so, if

$$(w + x)\,(3w + x)^2 = K\,(2w + x)^3, \qquad (19)$$

in which K is a co-efficient nearly constant.

Expanding both sides we have

$$9\,w^3 + 15\,x\,w^2 + 7\,x^2\,w + x^3$$
$$= K\,(8\,w^3 + 12\,x\,w^2 + 6\,x^2\,w + x^3);$$

from which we obtain four equations to determine the best value of K, viz.:—

$9 = 8\,K$	$K = 1·125$
$15 = 12\,K$	$K = 1·250$
$7 = 6\,K$	$K = 1·166$
$1 = K$	$K = 1·000$
Mean . .	1·135

The co-efficients of the two sides of equation (19) will be most nearly equal, when $K = 1·135$.

The constants used by Mr. Jevons and myself give

$$K = \frac{A}{B} = \frac{2622}{2314} = 1·133,$$

which is about the value required by the preceding considerations.

The curve denoted by Mr. Jevons' equation is an equilateral hyperbola, the co-ordinates being parallel to the asymptotes, and the origin taken upon the curve itself.

It is easy to see, from an inspection of Diagram No. 1, that a portion of such an equilateral hyperbola would coincide nearly with the true curve, and with the points determined by experiment.

Addendum.—Mr. Robert B. Hayward, of Harrow, has kindly called my attention to an error in my application of Law 1 to Mr. Jevons' first series of experiments in which different weights were thrown by hand. In applying Law 1 to these experiments, I assumed, in equations (1, 2, 3, 4), that the total work stored up in a revolving body is that of a body of equal weight, moving with the velocity of the centre of *oscillation*. I should have stated that it is the work of a body of equal weight moving with the velocity of the centre of *gyration*. If this error be corrected, the four equations become much simpler in form, and lead directly to the empirical formula used by Mr. Jevons, and also furnish a curve which corresponds very well with the experiments.

Let k denote the radius of gyration, and let the other symbols remain as before; we find the following equations, which are to be used instead of the first four already given.

$$(w + x)\, v^2 = \text{Const.} \tag{1}$$

$$v = V\frac{k}{a} \tag{2}$$

$$\frac{k^2}{a^2} = \frac{1}{3}\cdot\frac{3w + x}{w + x} \tag{3}$$

$$(3w + x) \times R = A \tag{4}$$

Mr. Jevons' eight experiments furnish twenty-eight equations to determine the value of x, and the mean of all the values is

$$x = 11{\cdot}1\text{lb.}$$

This value of x, when substituted in the eight equations furnished by (4), gives us the following values of A.

w	A
56 lbs.	329·5
28 „	351·8
14 „	364·2
7 „	338·9
4 „	337·5
2 „	318·9
1 „	325·0
½ „	342·1
Mean	338·49

If the mean values of A and x be used in equation (4), we find the following comparison of theory and observation:—

w	R (*observed*).	R (*calculated*).	*Difference.*
56 lbs.	1·84 feet	1·89 feet	−0·05 feet
28 „	3·70 „	3·56 „	+0·14 „
14 „	6·86 „	6·37 „	+0·49 „
7 „	10·56 „	10·55 „	+0·01 „
4 „	14·61 „	14·65 „	−0·04 „
2 „	18·65 „	19·79 „	−1·14 „
1 „	23·05 „	24·01 „	−0·96 „
½ „	27·15 „	26·86 „	+0·29 „

The curve of useful effect, deduced from equation (4) is

$$wR = \frac{Aw}{3w + x}.$$

This curve represents an equilateral hyperbola, whose equation, referred to its asymptotes as axes of co-ordinates, is

$$xy + 417{\cdot}4 = 0.$$

Diagram No. 4 shows this hyperbola, while the centres of the little circles show the several experiments.

This hyperbola, derived from the property of the centre of gyration, represents the observations very well; and it nearly coincides with the more complex curve derived from the centre of oscillation, shown in Diagram No. 1.

Mr. Jevons' empirical formula corresponds at once to equation (4), provided the quantity (q) be used to denote *one-third* of the weight of the arm instead of *one half*. His formula becomes, multiplying above and below by 3,

$$R = \frac{347{\cdot}1}{3w + 11{\cdot}7}$$

The weight of the arm and shoulder used in throwing weights, viz. 11·1lb. or 11·7lb., is considerably greater than the weight of the simple arm, 7·4lb., a result quite consistent with the fact that the scapular muscles move with the arm in this kind of exertion.

S. HAUGHTON

NOTES

AT a preliminary meeting held at King's College on Monday last, the Rev. Dr. Barry, Principal, in the chair, it was resolved that a fund for a Memorial to the late Dr. Miller, in connection with King's College as having been for thirty years the principal sphere of his labours, be at once raised by subscriptions in the College, and from the general public. It was further resolved to form a committee for the purpose of carrying out this resolution, and as soon as the committee is complete a meeting will be summoned to adopt such further measures as are necessary.

WE are glad to hear that Prof. Frankland has accepted the Presidency of the Chemical Society for the ensuing session.

A CIRCULAR has been issued by the Science and Art Department of the Committee of Council on Education, South Kensington, directing that in future all teachers certificated by the Education Department shall be allowed to earn payments on the results of the instruction of their pupils in Stage I. of Mathematics, according to the rules of the Science Directory, without having previously passed the qualifying examination required by § XXXIII. The Department has also issued the following amended programme of the examinations for the diplomas of the Royal School of Naval Architecture and Marine Engineering, which is to come into force at the examination to be held in April 1872, the examination in April 1871, being held according to the programme contained in the existing Directory of the School:—"Diplomas will be given to all persons, whether they have received their instruction at the school or not, who pass the final examinations of the school, provided that they give satisfactory evidence of having gone through the course of practical work recommended by the Council of the Institution of Naval Architects. These diplomas will be of two grades, according to the success of the candidate in the examination, the title of the higher grade being Fellow, and of the lower, Associate, of the Royal School of Naval Architecture." These examinations will be held annually towards the end of April. Candidates who have not been students of the school will be required to produce certificates that they have been engaged for three years, at least, in—(1) practical wood or iron ship-building in a dockyard; or (2) practical engine and boiler building in a dockyard, or in the works of a marine engineer; or (3) practical work as a draughtsman in a dockyard (or marine engine works), during which the candidate must have himself gone through the complete formation of the design of a ship (or of a marine engine), with the whole of the calculations included in it. Such candidates will also be required to give references as to character and good conduct before they are admitted to the examination. All such candidates must apply to the Secretary, Science and Art Department, South Kensington, W., not later than the 15th March in each year.

IN our notice last week of the attainments of the Senior Wrangler, we should have included the statement which we made some time since, that Mr. Hopkinson took the degree of D.Sc. at the University of London, in 1870, in two distinct branches, viz. Mathematics and Physical Optics, this being the first similar instance on record. Dr. Hopkinson has also attained the additional distinction which so often falls to the lot of Senior Wranglers, that of First Smith's Prize-man. The Second Smith's Prize has been awarded to Mr. Temperley, of Queen's College, bracketed fourth wrangler. It is stated that Dr. Hopkinson, being disqualified as a Nonconformist from sharing in the emoluments of the University, intends following his father's profession of engineer.

THE following are the Council and Officers of the new Anthropological Institute of Great Britain and Ireland:—President: Sir John Lubbock, Bart., F.R.S.; Vice-Presidents: Prof. Huxley, F.R.S., Prof. Busk, F.R.S., Mr. John Evans, F.R.S., Dr. Charnock, Dr. Barnard Davis, F.R.S., Mr. George Harris; Director: Mr. C. Staniland Wake; Treasurer: Mr. J. W. Flower, F.G.S.; Council: H. G. Bohn, Colonel Fox, Dr. Hyde Clarke, W. Blackmore, W. Boyd Dawkins, F.R.S., R. Dunn, David Forbes, F.R.S., T. M'K. Hughes, Dr. A. Campbell, S. E. Bouverie Pusey, W. C. Dendy, Sir D. Gibb, Bart., Dr. R. King, Capt. Bedford Pim, R.N., Rev. D. I. Heath, Dr. J. Beddoe, Dr. George Harcourt, Joseph Kaines, F. G. H. Price, and C. Robert des Ruffières. Secretary: J. F. Collingwood; Sub-editor of Journal: F. W. Rudler. A Special General Meeting of the Anthropological Society will be held at the rooms, No. 4, St. Martin's Place, on the 14th February, at half-past seven o'clock, for the purpose of authorising the trustees of the Society to transfer its funds and effects to the trustees of the "Anthropological Institute of Great Britain and Ireland," in pursuance of an agreement for union under that name between the Anthropological and the Ethnological Societies of London. On the same evening, at eight o'clock, will be held the first ordinary meeting of the Anthropological Institute, when Sir John Lubbock, Bart., President, will read a paper "On the Development of Relationships."

THE Anniversary Meeting of the Royal Astronomical Society will be held to-morrow at three, and that of the Photographic Society on Tuesday next at eight.

THE following lectures on Comparative Anatomy are to be delivered in the Theatre of the Royal College of Surgeons on Mondays, Wednesdays, and Fridays, at four o'clock, commencing on Friday, Feb. 17, by W. H. Flower, F.R.S., Hunterian Professor of Comparative Anatomy and Physiology. Eighteen lectures on the Characters, Structure, Functions, and Modifications of the Teeth and Allied Organs in the Mammalia. Essential characters and structure of teeth. Development and succession of teeth. Classification and nomenclature of teeth—Dental formulæ. Modifications of the characters of the teeth in the different groups of the mammalia. Teeth of Man. Teeth of *Simiina*—Old-World Monkeys and New-World Monkeys. Teeth of *Lemurina*. Teeth of terrestrial *Carnivora*—Dogs and allied forms; Cats and allied forms; Bears and allied forms. Teeth of *Pinnipedia*—Sea-Bears and Seals; Walrus. Teeth of *Insectivora*—Hedgehogs, Moles, Shrews, &c.; Galeopithecus. Teeth of *Chiroptera*—Frugivorous Bats, Insectivorous Bats, Blood-sucking Bats. Teeth of *Rodentia*—Hares, Guinea Pigs, Porcupines, Rats, Squirrels, &c. Teeth of *Cetacea*—Odontocetes or Toothed Whales; Dolphins, Porpoises, Narwhal, Sperm-whale, Ziphius, and allied forms; Zeuglodonts; Mystacocetes or Whalebone Whales, rudimentary Teeth; Structure and function of baleen or whalebone. Teeth of *Ungulata*—Perissodactyles: ancient and modern forms, Palæotherium, Horse, Rhinoceros, Tapir; Artiodactyles: Pigs, Hippopotamus, Anoplotheridæ, Camels, Chevrotains, and Pecora (Deer, Giraffe, Antelopes, Sheep, Goats, and Oxen). Teeth of Hyrax, of Toxodon, of Typotherium, and other anomalous forms. Teeth of *Proboscidea*—Elephant, Mastodon, Dinotherium. Teeth of *Sirenia*—Dugong and Manatee. Teeth of *Edentata*—Sloths, Anteaters, Armadillos. Teeth of *Marsupialia*—Opossums, Thylacine, Dasyures, Perameles, Phalangers Kangaroos, Wombats; Fossil Marsupials. Value of dental characters in drawing inferences as to the affinities and habits of extinct animals. Horny teeth of *Monotremata*—Ornithorhynchus. The lectures are free to all who take an interest in the subject.

INTELLIGENCE has been received of the death of Dr. F. A. G. Miquel, Professor of Botany at the University of Utrecht and Director of the Botanic Gardens at Leyden, one of the few remaining distinguished systematic botanists on the Continent, and greatly esteemed by all scientific visitors to Holland for his generous hospitality and kindly nature. He was the author of several monographs, and had written largely on the botany of the Netherland-Indies, especially Java and Surinam; and also on that of Japan, which has been much worked out by Dutch naturalists; but will be best known by his magnificent "Annales Musei botanici Lugduno-batavi," in four folio volumes, with splendid illustrations. He was one of the foreign members of the Linnean Society of London.

A STATEMENT having appeared in the *Globe* that the M.A.'s of the University of London have made a representation to the authorities that the examinations for degrees are too stringent, and that it is probable that the standard will be lowered; we are authorised to state that the report is entirely incorrect; no such representation has been made, and no proposal for lowering the standard of the degrees is under the consideration of the Senate of the University.

IN consequence of a report made to the Senate of the University of London by the Examiners in Physiology, setting forth the insufficiency of the present *viva voce* examination as a test of the practical acquaintance of candidates with histology and practical physiology, an important alteration has been made in the regulations of the First Bachelor of Medicine Examination. The alteration will take effect in the year 1872 and subsequent years, and the Registrar has been directed to notify to the various medical schools in connection with the University, that the Candidates for the first Examination in Bachelor of Medicine will be required to pass a practical examination in Histology. The requisite provision is to be made in the University building for carrying out a plan which has been suggested by the Examiners, and approved of by the Senate, and of which the following outline is given by the *British Medical Journal*:—The candidates are to be examined in convenient batches, placed in a suitable room, fitted up with microscopes, glasses, reagents, needles, scissors, and razors. Each student is to have placed before him a few characteristic mounted specimens, and portions of fresh tissue or tissues prepared for minute examination, all numbered and carefully selected, and to be given three hours in which to examine and report upon the specimens presented to him, as well as to mount certain specimens of particular organs or tissues, as may be required by the Examiners. In this way, it is felt, the possession of mere book-knowledge by the candidate will be at once disclosed, and the physiological examination will be made a real and satisfactory one.

A ZOOLOGICAL RECORD ASSOCIATION has been established for the purpose of continuing the *Record of Zoological Literature* (an annual volume, containing an abstract of, and an index to, all that has been done in zoology during the previous year), which has been held in such high esteem by working zoologists that for some time past the British Association has been induced to vote an annual grant of 100*l*. in its support. Owing, no doubt, to the fact of its utility not being sufficiently known to the public, the undertaking has not hitherto proved a financial success. The new Association, which includes, we understand, all the leading zoologists of the country, hopes to have better luck, and in a few days it is expected that its programme will be before the world. Mr. Stainton, F.R.S., is the Secretary.

THE New York Association for the Advancement of Science has recently elected officers for the ensuing year, and the *American Chemist* notes that on looking over the list it finds that, among the names of fifteen officers, it does not recognise a single man of science. Six are clergymen, three are physicians. Though it is pleasant to see these men anxious to promote the cause of science, a little sprinkling of scientific men would tend to increase the confidence of the public in the discussions of the society.

THE *American Chemist* states that Prof. William Griffis, of Rutgers College, has gone to Japan as Professor of Chemistry and Natural Philosophy in the University of Japan.

THE following scientific appointments to American Colleges have recently been announced :—Mr. George C. Swallow, to the chair of Agriculture in the University of Missouri ; Mr. Charles H. Wing, to the Professorship of Applied Chemistry, Dr. Alonzo M. Chase, as Instructor in Analytical Chemistry, and the Rev. J. J. Brown, to the chair of Physics, in Cornell University ; Mr. T. H. Staver has been elected Professor of Agricultural Chemistry at Harvard University ; and Mr. Albert H. Chester has been appointed to the Childs Professorship of Agricultural Chemistry in Hamilton College.

THE Legislature of Colorado, at its last session, appropriated thirty-nine hundred dollars for a building for a school of mines. The corner-stone of that building was laid on Monday, August 15, 1870, by Bishop Randall, in the presence of a large assembly of people.

THE *Scientific American* states that the Board of Trade of the city of Buffalo has obtained a franchise and organised a company to be styled the Oxyhydrogen Gas Company, having for its object the introduction of the oxyhydrogen gas light into that city. A committee of investigation has visited the oxygen gas works in New York, and with the information thus obtained we are informed that the work is to proceed at once. It would appear that Buffalo is to be the first city in America to adopt this splendid light. The experiment is an important one, and its success will be watched with considerable interest by gas consumers in this country and America.

IT may be interesting to record that during the two mid-winter months of December 1870 and January 1871, the average temperature of the air at Blackheath was, according to Mr. Glaisher's tables, exactly 5° F. below the mean of the last fifty years. On 46 days the temperature was below the average, and above the mean on only 16 days, the mean for the 24 hours having been below the freezing-point on 27 days. The lowest average was on December 25th, when it fell as low as 18·9°, or 18·7° below the mean of the last fifty years. During nearly the whole of January the weather was also exceptionally warm in the neighbourhood of London ; in the midland and eastern counties, the depression would be considerably greater.

THE *American Chemist* for January announces that it commences its existence with that number as an independent journal, devoted to Theoretical, Analytical, and Technical Chemistry. The articles, both extracted and original, among which is a curious one on Assaying one hundred and thirty years ago, promise a supply of varied and useful information. It proposes to present its readers with abstracts of all papers published in America or elsewhere, which involve chemical principles in their discussion.

THE *British Medical Journal* states that two additional cases illustrating the efficacy of the injection into the veins of ammonia in snake-bite, on the plan of Professor Halford, are published in the Melbourne papers. They are reported with great decision of statement as to the immediate benefits conferred, but without the scientific precision of detail which is needed, and which will, we hope, be forthcoming.

A MEETING was held in the Town Hall, Stranraer, on Friday, the 5th January, to discuss the advisability of establishing cheese factories in the county on the American system, and a committee was appointed to inquire into the details regarding the management of the Derbyshire cheese factories, and to report at a future meeting.

M. LITTRÉ has received a letter from M. Gambetta, praising him highly for his invaluable works, and nominating him as Professor of History to the Bordeaux Polytechnic School. The letter was published by public authority in the *Moniteur*.

THE new fuel invented for Paris is more substantial than had been supposed. It is the asphalt used for coating the side-ways of the streets. The total length of *trottoirs* is about two million yards, the breadth two yards, and the thickness half an inch, so that the cubic measurement of asphalt ready for use is 555,550 cubic yards. It is mixed with about half of its weight of sand, which reduces the real weight of asphalt to 277,777 cubic yards. It is difficult to burn asphalt without being suffocated with smoke. But all these drawbacks can be met successfully by scientific skill and ability. M. Le Troost, directorof the Grenelle Gas Works, has erected furnaces for using tar as fuel in the distillation of tar. Tar is sufficient without the help of any other fuel to prepare gas for ordinary purposes or for inflating balloons. These furnaces were working successfully from the beginning of November, and this success has probably led to the idea of using asphalt as fuel for ordinary purposes.

ONE rather singular invention for remedying the actual want of fuel in private houses became very popular in Paris during the siege. They prepare cylinders of clay impregnated with bituminous substances ; these combustible cylinders are used like the ordinary charcoal which is necessary in Parisian cookery. The earthy matters, of which the proportion is not greater than necessary, remain in the furnaces like ashes left by the combustion of charcoal. It is stated that it is proposed to continue the use of this kind of artificial fuel.

THE *Academy* states that the great attraction of the geological portion of the St. Petersburg Museum consists in one entire gallery of mammoth remains, probably including many nearly entire skeletons, the bones of all of which are in a remarkably fresh state of preservation. Some years since (owing to the exertions of Sir Antonio Brady), an almost entire mammoth's skull, with tusks of colossal proportions, was obtained at the brick-pits at Ilford, in the Thames Valley brick-earth, and now adorns the geological gallery of the British Museum. Since the appointment of M. Dupont to the post of keeper in the Brussels Museum, the almost entire skeleton of a mammoth, found some time since, but neither repaired nor mounted, has been diligently mended up bit by bit, till they are able now to boast the possession of the best example of *Elephas primigenius* out of St. Petersburg. One is struck with the comparative height and slenderness of the mammoth's skeleton as compared with the modern elephant, and it seems probable that he was a more active and a lighter-built beast than the Asiatic or African species. It is to be hoped that the British Museum collection will ere long be enriched by the addition of a skeleton of the Siberian mammoth. The execution of the fortifications around Antwerp has led to the discovery, not only of elephants' and mastodons' remains, but of a most wonderful series of cetacean bones. These are now arranged in a fine gallery in the Brussels Museum, which, under the direction of M. A. de Borre, bids fair to be one of the most attractive of Continental institutions.

SHOCKS of earthquake were felt in Scinde on the 12th November.

ON the 24th October at 1.40 A.M. a smart shock of earthquake was felt at Yokohama, with a deviation from E. to S.W. The shock was remarkable for long duration.

THE NATURE OF THE EARTH'S INTERIOR*

IN a previous discourse on volcanoes,† I directed attention to the phenomena of volcanic action, specially considered in relation to the part which such igneous or internal forces have played in determining the grand features of the external configuration of the sphere upon which we live.

If now we follow up this subject still further, it will naturally lead to an inquiry into the nature of the internal substance of the globe itself, within which the foci of such agencies must be situated; quite independent of this, however, I have little doubt but that many of you must at some time or other have already asked yourselves the question—What does the central mass of the earth beneath us consist of?

The answer which, in the first instance, would, I imagine, be most likely to suggest itself to your minds, would be that it consisted of solid stone, such as you see forming the body of its mountains, the foundations of its continents, and the rock basins which contain its seas. The belief in such an hypothesis would, however, be rudely shaken by the first personal experience of the shock of an earthquake, the sight of a volcano in eruption, or the consideration of the immense faults which have dislocated many parts of the solid land; since, so far from disposing us to regard the ground under us as entitled to the appellation of the *terra firma*, so commonly used by the ancients, the study of such phenomena could not but suggest grave doubts in our minds as to whether the earth was after all anything like so solid or stable as we at first sight felt inclined to imagine.

But very little inquiry into the subject is necessary, however, to convince any one of the great difficulties in the way of obtaining a satisfactory answer to this question, and to prove that at present we do not have at our command sufficient data or evidence to enable us to arrive at a thoroughly conclusive solution of this most interesting problem.

As the rapid advances made by the natural sciences are, however, daily adding to our information on this subject, and thus enabling us to correct or modify our previous deductions, so as to form a more and more trustworthy opinion on the nature of those parts of our globe, which, from their position, must always remain inaccessible to our powers of direct observation, I have imagined that a short sketch of the present state of our knowledge concerning the probable constitution of the interior of the earth might prove interesting.

In treating this subject, we will first consider what has already been done in the way of direct examination of the earth's substance in depth; yet when it is remembered that the mean diameter of our planet is some 7,912 miles, whilst the greatest depth hitherto attained by man's direct exploration has not even yet reached one mile from the surface downwards; this disproportion appears so enormous as to render it self-evident, in the pursuit of this inquiry, especially as regards the more central portions of the earth, that we must in the main rely upon data furnished by calling in the aid of the natural sciences. The direct examination of the exterior of the earth, even when restricted to this depth, does nevertheless furnish us with many important data from which to start in this to a great degree speculative inquiry, and to some of these we shall now direct attention.

It must first of all be remembered that all the rocks which we meet with at the surface, and which compose so much of the solid exterior of our globe as is actually known to us, may be arranged under two principal heads, viz., the volcanic or endogenous rocks, *i.e.* those formed within the body of the earth itself, and the sedimentary or exogenous, *i.e.* those rocks formed, or rather reconstructed upon its surface, out of the *débris* of previously existing rocks arranged in beds or strata by the mechanical action of water.

It was long taken for granted by geologists that the lowest sedimentary strata, in their normal or in a more or less altered condition, rested directly upon granite, which was for a long time regarded as the foundation upon which they, in the first instance, had been deposited, since this rock was looked upon as the oldest of all, and as representing the primeval or original surface covering of the earth. Later researches, however, have proved this hypothesis to be untenable, since it appears that no instance of a granite has as yet been met with in nature, which if followed up, does not at some place or other break through, and alter or disturb more or less, the stratified rocks in immediate contact with it, so that it naturally follows that such stratified rocks must have preëxisted on the spot, or in other words, that they were older in geological chronology than the granite which came to disturb them.

In the present state of geology, however, it is utterly impossible for us to point out any variety of rock whatsoever as the one which may have served as a foundation upon wh ch the oldest sedimentary rocks were originally deposited, in fact the oldest rocks which we know of at present are themselves sedimentary rocks (mostly in an altered condition) belonging to the Laurentian series in Canada, and as yet it has not been found out what these sedimentary beds may in their turn rest upon, *i.e.*, what is actually below them.

As therefore we have not as yet been able to reach down to investigate directly any rocks lower in the geological series than those pertaining to the Laurentian formation, we will now turn to the volcanoes, in order to examine the mineral products which they bring up for our consideration, from depths vastly beyond those which we can ever hope to reach directly. What volcanoes teach us with regard to the nature of the earth's interior, at a depth from which they derive their supply of mineral matter, may be summarised as follows:—

That at this depth, the earth's substance exists in a state of perfect molten liquidity, forming as it were a sea of molten rock, analogous in character to the eruptive rocks which have broken through the earth's crust in former times. Secondly, that the mineral products ejected from volcanoes are very similar to oneanother in chemical and mineral constitution, no matter from what part of the globe they may emanate from. And, lastly, that from the same volcanic orifice, and during the same eruption, lavas of two totally different classes may be emitted, viz., the light, acid, or trachytic lava, analogous to the granites, felsites, &c., of the oldest period, and the heavy basic or pyroxenic lava, all but identical with the dark basaltic or trappean rocks commonly met with as dykes, &c., disturbing most of the different sedimentary formations.

Another deduction from the study of volcanic phenomena, indicating that at a certain depth below their surface they must be in connection with a continuous sea of molten lava, is based upon the influence which the moon appears to have on volcanic eruptions; this opinion seems to have been confirmed by the observations of Prof. Palmieri made during the last eruption of Vesuvius, on which occcasion he reported that distinct tidal phenomena could be recognised, thereby indicating that the moon's attraction occasioned tides in the central zone of molten lava, in quite a similar manner as it causes them in the ocean. A further corroboration of this view is seen in the results of an examination of the records of some 7,000 earthquake shocks which occurred during the first half of this century, compiled by Perry, and which, according to him, demonstrate that earthquakes are much more frequent in the conjunction and opposition of the moon than at other times, more so when the moon is near the earth than when it is distant, and also more frequent in the hour of its passage through the meridian.

Returning now to the more direct examination of the superficial parts of the earth, we find that the results of mining operations have also thrown considerable light, not only on the mineral nature of the rocks encountered in depth, but also upon some of their physical conditions. A numerous set of experiments made in deep mines in various parts of the world, often far distant from one another, has most conclusively proved that the temperature of the earth, at least as deep down from the surface as has been explored by man, increases in direct ratio as we descend towards its centre. Other observations on the temperature of the water from deep-seated and hot springs, and from artesian wells, fully confirm the experiments made in mines, and show that the temperature of the water furnished by them also becomes higher in proportion to the depth of the source from which it is derived.

As might naturally be expected, the interference of local causes renders it a matter of considerable difficulty to determine the true mean general rate of such increase in temperature of the earth's substance downwards; still, in the main, observers all agree in placing it at somewhere between $1\frac{1}{2}°$ and $2\frac{1}{2}°$ degrees F. for every hundred feet in depth, so that we cannot be far wrong, if for our purpose we estimate it at 2° F. for every hundred feet in depth, or a rate which amounts to 121° for each geographical mile nearer the earth's centre. Since no facts are at the present time known which can in any way invalidate the supposition that this or a somewhat similar rate of increase in temperature holds good in still greater depths, it is perfectly correct and justifiable reasoning to assume that such is actually

* Substance of a Lecture delivered for the Sunday Lecture Society on January 29.

† See NATURE, vol. ii. p. 283.

the case, and therefore a simple calculation will show that at a depth of about twenty-five geographical miles from the surface downwards a temperature of about 3,000° F. should be attained, which would represent a heat at which iron melts, or one sufficient to keep lava in a state of perfect molten liquidity at the surface of the earth. As it must be remembered, however, that at this depth the substance of the earth would be exposed to the pressure of the superincumbent mass, and as it has been shown by experiment that many substances become more refractory—*i.e.*, require a greater degree of heat to melt them—when exposed to pressure than when at the surface, the above calculation will have to be modified considerably in order to meet this condition. Unfortunately, we have not as yet sufficient data at command to enable us to estimate the true ratio in which the melting points of such rocks would become elevated by pressure; yet we may safely take it for granted, after allowing far more than the maximum rate of increase, deduced from the experiments of Bunsen and Hopkins, that we should not require to sink so deep again in order to attain a temperature fully sufficient to keep such substances in a state of fusion, or, in other words, this deduction necessitates the supposition that the solid rock crust of the earth cannot, at the utmost, be more than 50 miles in thickness.

If we now reason from the above data as premisses, it will follow as a natural consequence that our globe must in reality be a sphere of molten matter surrounded by an external shell or crust of solid matter, of very insignificant thickness when compared to the diameter of the entire globe itself; or, in other words, this deduction represents exactly such a state of things as would ensue in the event of a sphere of molten matter becoming consolidated on its exterior by the cooling action of the external atmosphere; and the figure of the earth itself, which is an ellipsoid of revolution, *i.e.*, a sphere somewhat flattened in at the poles, but bulging out at the equator, being that which a plastic mass revolving round its own axis would assume, is regarded by natural philosophers in general as all but conclusive evidence, that the earth at an early period of its history must have been in a fluid condition.

Although the doctrine that the earth is a molten sphere surrounded by a thin crust of solid matter was all but universally taught by geologists, there have of late years been brought forward several arguments to the contrary, which apparently are more in favour of its being a solid or nearly solid mass throughout, and these arguments are fully entitled to our consideration, as our object is not to defend any particular theory, but to arrive as nearly as we can at the truth. I will, therefore, in the first place proceed to scrutinise all which has been brought forward in opposition to the older hypothesis, and then to consider whether any other explanation yet advanced is more in accordance with the facts of the case.

First of all we have to answer the question as to whether it is possible for such a thin crust to remain solid, and not at once to become melted up and absorbed into the much greater mass of molten matter beneath it? This would doubtless be the case, if the central fluid mass had any means of keeping up its high temperature, independently of the amount of heat it actually possessed when it originally assumed the form of an igneous globe. This question, however, in reality answers itself in the negative, since it is evident that no crust could even commence to form on the surface, unless the sphere itself was at the moment actually giving off more heat from its outer surface to the surrounding atmosphere than it could supply from its more central parts, in order to keep the whole in a perfectly fluid condition, so that when once such a crust, however thin, had formed upon the surface, it is self-evident that it could not again become melted up or re-absorbed into the fluid mass below.

This external process of solidification due to refrigeration would then continue going on from the outside inwards, until a thickness of crust had been attained sufficient to arrest or neutralise (owing to its bad conductibility of heat) both the cooling action of the surrounding air and the loss of more heat from the molten mass within; and thus a stage would soon be arrived at when both these actions would so counterbalance one another that the further cooling down of the earth could be all but arrested: a condition ruling at the present time, since the earth-surface at this moment, so far from receiving any or more than a minute amount of heat from the interior, appears to depend entirely, as regards its temperature, upon the heat which it receives from the sun's rays.

We have next to consider the argument that, if the earth's exterior was in reality only such a thin covering or crust, like the shell of an egg, to which it has often been likened, that such a thickness would be altogether insufficient to give to it that stability which we know it to possess, and that consequently it could never sustain the enormous weight of its mountain ranges, such as, for example, the Himalayas of Asia or the Andes of America, which are, as it were, masses of rock piled up high above its mean surface-level.

At first sight, this style of reasoning not only appears plausible, but even seems to threaten to upset the entire hypothesis altogether. It requires but little sober consideration, however, to prove that it is more, so to speak, sensational in character than actually founded on the facts of the case; for it is only requisite for us to be able to form in our minds some tangible idea of the relative proportion which the size of even the highest mountain bears to that of the entire globe itself, to convince us, if such a crust could once form and support itself, that it could with ease support the weight of the mountains also. The great Himalaya chain of mountains rises to a maximum altitude of 31,860 feet, or six miles above the level of the sea; and if the earth could be seen reduced in scale down to the size of an orange, to all intents and purposes it would look like an almost smooth ball, since even the highest mountains and deepest valleys upon its surface would present to the eye no greater inequalities in outline than the little pimples and hollows on the outside of the skin of an ordinary orange. If this thin crust of the earth can support itself, it is not at all likely to be crushed in by the comparatively speaking insignificant weight of our greatest mountain chains, for in point of fact it would be quite as unreasonable to maintain such a supposition, as to declare that the shell of a hen's egg would be crushed in by simply laying a piece of a similar egg-shell upon its outside.

That a very thin spheroidal crust or shell enclosing a body of liquid matter such as an ordinary fowl's egg, does possess in itself an enormous degree of stability and power to resist pressure from without, is easily demonstrated by merely loading a small portion of its surface with weights as long as it does not give way under them. Even when placed on its side (or least strong position) it was found that a portion of the shell only one quarter of an inch square would sustain several pounds weight without showing any symptoms of either cracking or crushing; or, in other words, this simple experiment indicates that if the external crust of the earth was but as thick and strong in proportion as an egg-shell, it would be fully capable of sustaining masses equal in volume and weight to many Himalayas piled up one atop of another, without any danger whatever to its stability.

The next argument which has been advanced against the probability of the major part of the earth's substance being in a fluid condition, is one based altogether upon astronomical considerations. It having been demonstrated when two clocks are set agoing, the pendulums of which are similar to one another in all respects except that whilst the bob of the one is solid, that of the other is hollow and filled with mercury, that the latter will swing somewhat faster, and consequently the clock gain time upon the former. The late Mr. Hopkins, of Cambridge, applied this observation to the consideration of movements of the earth in space, and by a very elaborate course of mathematical reasoning and calculation, demonstrated that the earth, if not quite solid, must be nearly so, since according to his results, if it was merely a comparatively thin shell filled with liquid matter, the ratio of certain of its movements (the precession or nutation) would differ considerably from what they are actually known to be, and these conclusions appeared to be confirmed by the subsequent calculations of Sir William Thomson and Archdeacon Pratt. Although grave doubts suggested themselves as to the correctness of the values used in these calculations for two of their most important elements, viz., the condensing action of pressure and the expanding action of the very high temperatures within the globe—both of which have not as yet been determined with any certainty, and although it might also be surmised that the conditions of a pendulum bob of polished glass filled with heavy slippery mercury swinging at the end of a rod must be extremely different from those of a nearly spherical globe filled with viscid sticky lava revolving around its own axis; still geologists felt themselves quite unable to answer the arguments of the astronomers and mathematicians, and since none of them appeared to be sufficiently versed in either astronomy or mathematics to be able to submit the method of reasoning or the calculations to any strict scrutiny, they felt themselves, reluctantly no doubt, compelled to bow to the decision of such eminent authorities.

So stood the matter until the summer of 1863, when, fortunately for the advancement of this inquiry, M. Delaunay, now Director of the Observatory at Paris, an authority equally eminent as a mathematician and an astronomer, was induced to undertake the reconsideration of this problem; a labour which has not only resulted in altogether reversing the above decision, and demonstrating the complete fallacy of the premisses upon which so much elaborate reasoning had been expended, but which proved conclusively by experiment that a sphere filled with liquid matter would, under circumstances such as are present in the case of the earth, behave in precisely the same manner as an entirely solid one, and, consequently, that the fact of the earth being either solid or liquid in its interior could neither have any influence whatever on the rate of precession or nutation, nor be of any use as a means of deciding as to the real or approximative thickness of the earth's crust.

It may also be added that the conclusions arrived at by Mr. Hopkins, even when supported by Sir William Thomson and Archdeacon Pratt, were not universally acquiesced in; the celebrated German physicist, Helmholtz, amongst others, was not satisfied as to their correctness, and in opposition to the deductions of Sir William Thomson that the earth's crust must be some 1,000 miles in thickness, we have the entirely opposite conclusions of Mr. Henessey, whose calculations tend to show that the earth's crust cannot be less than eighteen miles or more than 600 miles in thickness. We may now, however, fairly conclude that all the objections as yet advanced from an astronomical point of view against the theory of the fluid condition of the interior of our planet, have been invalidated or explained away.

The only other argument in favour of internal solidity is one which bases itself upon the law, announced upon theoretical considerations by Professor Thomson in 1849, that the fusing points of bodies must become more elevated when subjected to pressure, or, in other words, that under the influence of pressure, bodies will require more heat to melt them.

Starting from this, Bunsen argued that the earth could not be other than solid to the core, since the enormous pressure accumulated at the centre would cause its internal substance to become so infusible that it could not remain in a molten state. To a certain extent this law was corroborated by the experimental researches of Bunsen and Hopkins, made upon some of the easily fusible substances like wax, spermaceti, paraffin, and sulphur; but as far as the later experiments went, it was not confirmed either in the case of metallic substances, nor did it appear to hold true with other than the more easily compressible bodies.

In the case of the earth, therefore, the conclusions of Bunsen cannot be accepted, since we have to deal with materials to which, as yet, this law has not been proved to apply; still, assuming, as seems most probable, that the materials composing the earth's mass do become to some extent more and more infusible according as they approach nearer to its centre, it must, on the other hand, be remembered that this would be more or less neutralised by the expansion which these substances would undergo from the action of the internal heat; and as incontrovertible evidence has been produced to prove that the temperature of the earth downwards from the surface increases in direct ratio with the depth, it seems most probable that the combined effects of expansion and elevated temperatures would more than counteract any tendency to solidification due to the effects of pressure.

Having now taken into consideration the various objections which have been urged against the theory of the earth's internal fluidity, as well as devoted some consideration to the opposing view of its solidity, it will be noticed, if we pass in review some of the distinctive features of the two hypotheses, that the former theory is a legitimate deduction from the data afforded by the direct study of the earth itself, whereas the latter, on the contrary, instead of making the explanation of the earth's phenomena its starting point, devotes itself almost exclusively to the task of proving that it could not be fluid.

Thus, how is it possible, if the earth's mass be solid throughout, to account for the great upheavals or sinkings down of large portions of the rock formations which compose its external crust? Do not these phenomena lead to the direct inference that the external crust cannot, by any possibility, rest in depth upon an unyielding mass of matter in the solid state, but that it must necessarily be superposed upon some more or less fluid substance which by its mobility can, when some one portion of the crust above sinks down, become displaced, and so make room for it by elevating, or, as it were, floating up some other part of the same?

In like manner the hypothesis that the earth is essentially solid necessitated that the phenomena of volcanoes should be explained upon the supposition that they had their sources in numerous small isolated local basins of molten rock scattered over the surface of the globe; a view which is altogether inconsistent with the results of chemical and mineralogical investigation, which proves that the ejected products are identical in constitution even if taken from volcanic vents the most distant from one another, nor does such a theory attempt to explain the tidal phenomena of volcanic outbursts and earthquakes previously alluded to.

So far, therefore, as we have gone into this subject, we may regard the balance of evidence as proving that at a depth of about fifty miles or less from the surface, there exists a continuous zone of molten rock or lava, such as is brought up to the surface by volcanic eruptions. Let us now consider how deep this zone or stratum of molten matter is likely to extend, and also what forms the more central mass of the earth below it.

In order to answer these questions we must look to other than direct evidence, and first of all must inquire whether the consideration of the mean density, or in other words the actual weight, of the earth itself, can throw any light upon these abstruse points. The consideration of the attraction which bodies exert upon one another in the ratio of their magnitude, has enabled the physicist to effect the at first sight apparently impracticable task of determining the entire weight of the earth itself, but it is out of our province to describe the mode of doing so, and we must content ourselves by accepting as a fact the results of such investigations, which prove that the total weight of our planet is as near as possible $5\frac{1}{2}$ times the weight of a similar globe of pure water. Knowing now that the mean density, or specific gravity, as it is also called, of the earth, is $5\frac{1}{2}$, and also from direct experiment that the mean density of the entire solid rock forming its external crust cannot be higher than $2\frac{1}{2}$, or less than half that of the entire sphere, it naturally follows that the central parts must be very much more heavy in order to account for so high a mean figure as $5\frac{1}{2}$, and it has been calculated that if we suppose that the earth was composed of three concentric portions of equal thickness, each in turn increasing in density towards the centre in arithmetical progression, we should then have an outer circle of specific gravity $2\frac{1}{2}$, or as heavy as rock, an intermediate zone of 12, or as heavy as quicksilver, and a central nucleus of about twenty times the density of water, or as heavy as gold.

This increase of density has sometimes been erroneously represented as entirely due to the effects of the enormous pressure of the superincumbent mass; but this supposition is quite untenable, since the tendency of all the numerous experiments made in this direction has been to prove that no substances can be compressed or condensed to an indefinite extent, since what may be termed their approximative maximum density is soon attained, beyond which the effects of pressure become so much smaller and smaller in proportion to the force applied, that at last the further condensation effected by still greater pressure is all but inappreciable. Besides this, it must not be forgot that the crust of the earth is a species of dome like the shell of an egg, which supports itself without resting or floating upon its fluid centre; and further that the earth's high internal heat, by causing the materials which compose it to expand, must also counteract the effects of superincumbent pressure, so that when all these facts are taken into due consideration, it appears quite evident that the materials which actually form the mass of the interior must be infinitely denser than any of the rocks met with on the surface, and that they must be metallic in their nature, since no other bodies are known which could at all fulfil these conditions of density.

If now we suppose that the earth's interior is composed of a series of concentric zones or layers made up of substances which are of more and more dense nature as they are situated nearer the centre, and that the external one is rock of a density of 2·5, a calculation will show that the centre or nucleus will be about 10, or as heavy as silver. If now we suppose that the zone of molten lava, which we have already concluded must exist at a depth of about 50 miles below the surface, has a density of 3, or say even 4, to give the fullest allowance for the condensing effects of superincumbent pressure, then we should find by calculation that this zone could not extend deeper than about 400 miles, since below this depth the matter would be so heavy that its density can only be explained on the supposition that it is made up of metallic compounds, and as the density of the still lower zones would continue to increase up to the very centre of the earth, the inference is that the whole of this great central mass situated at a distance of some 450 miles or less below the surface, is actually formed of metals and their compounds.

Whether this great central metallic nucleus is fluid or solid may next be inquired into. According to Bunsen's theory previously alluded to, it ought to be solid, for owing to the enormous pressure to which it would be exposed, the solidification of the molten sphere should first commence at the centre. This view would be quite correct if the earth was composed of highly compressible non-metallic materials; but since this is not the case, and since, as before alluded to, the experimental data already obtained indicate that neither the metallic nor the less compressible substances become more refractory in proportion to the increase of pressure, we are more justified in assuming that the central nucleus also must be in a fluid condition, and the more so, not only because we know that metallic compounds are as a rule infinitely more fusible than rock silicates, but also as the well-known high temperature of the earth's interior would, by its expanding action, tend to counteract the effects of the pressure

In summing up this inquiry, the balance of evidence appears to me to be decidedly in favour of the hypothesis that the interior of our earth is a mass of molten matter arranged in concentric layers or zones according to their respective densities, and the whole enclosed within a comparatively thin external crust or shell.

DAVID FORBES

SCIENTIFIC SERIALS

THE *American Naturalist* for January opens with a long paper by Prof. J. S. Newberry "On the Ancient Lakes of Western America: their Deposits and Drainage," which is stated to be a chapter from Dr. Hayden's forthcoming "Sun-pictures of the Rocky Mountains." Prof. Newberry states that the wonderful collection of fossil plants and animal remains brought by Dr. Hayden from the country bordering the Upper Missouri has been shown, by his observations and the researches of Mr. Meek, to have been derived from deposits made in extensive fresh water lakes, lakes which once occupied much of the region lying immediately east of the Rocky Mountains, but which have now totally disappeared. The sediments that accumulated in the bottom of these old lakes show that in the earliest periods of their history they contained salt water, at least that the sea had access to them, and their waters were more or less impregnated with salt, so as to be inhabited by oysters and other marine or estuary mollusks. In due time the continental elevation which brought all the country west of the Mississippi up out of the widespread Cretaceous sea raised these lake-basins altogether above the sea-level, and surrounded them with a broad expanse of dry land. Between these lakes were the areas of dry land covered with luxuriant and beautiful vegetation, and inhabited by herds of elephants and other great mammals, such as could only inhabit a well-watered and fertile country. Prof. Newberry's explanations throw much light on that remarkable feature of the western side of the great continent, the canons formed by the rivers, like the stupendous one of the Colorado, nearly 1,000 miles in length and from 3,000 to 6,000 feet in depth, with almost perpendicular sides. The Rev. A. P. Peabody contributes an account of the Chinese in San Francisco; Mr. H. Willey, a paper on Lichens under the microscope, with wood-cuts which very well illustrate their mode of vegetation and reproduction; and Dr. A. P. Barnard, a description of a new form of binocular for use with high powers of the microscope. The shorter articles and *Natural History Miscellany* contain, as usual, much interesting information.

The *Journal of Botany* for February commences a series of papers which will be very useful to systematic botanists; an alphabetical catalogue of the new genera and species of plants published during 1870 in the English botanical and gardening journals, not including the "Journal of the Linnean Society." The present number only carries the list down to *Dracontium*. Mr. J. G. Baker continues his monograph of the genus *Xiphium*, and Dr. Hance contributes an article on the so-called "olives" of Southern China, which he states to be produced by two species of *Canarium*, trees from twenty to thirty feet high, largely grown in the neighbourhood of Whampoa. The stones are beautifully and elaborately carved by the Chinese as ornaments, and, when set in gold, form exceedingly handsome brooches or bracelets. Two articles of special interest to systematists are Prof. Dyer and Dr. Trimen on *Polygonum nodosum*; and Mr. W. P. Hiern on the form and distribution over the world of the Batrachian (or aquatic) section of *Ranunculus*. There is also the usual section of short Notes and Queries.

SOCIETIES AND ACADEMIES

LONDON

Chemical Society, February 2.—Prof. Williamson, F.R.S., President, in the chair. The following gentlemen were elected Fellows: R. J. Friswell, R. F. Humiston, M.D., A. H. Mason, I. R. Justin. Prof. Frankland, F.R.S., read a paper "On the Development of Fungi in Potable Water." He began by alluding to the experiments Dr. Heisch had made some months back with waters contaminated with sewage matter. When to such waters some sugar was added, very soon a kind of fermentation ensued, and a rich fungoid growth made its appearance. Prof. Frankland has now repeated and extended these experiments and arrived, with one or two exceptions, at the same results. But in the course of his researches he encountered some reactions which revealed to him that the presence of sewage matter in saccharic water is in itself not sufficient to produce fungoid growth, but that the presence of phosphates in some form is indispensable to such production. Prof. Frankland further found that the germs which give rise to the development of fungi need not necessarily come from sewage contamination, but that they may be derived from the atmosphere. Finally, he found that animal charcoal does not remove those germs. Dr. Frankland thinks that the sugar test of Dr. Heisch for the detection of traces of sewage contamination may be turned into a very delicate reagent for the detection of minute quantities of phosphates; for when these defy the power of the usual laboratory tests, they yet are capable of feeding those germs and thus giving rise to the fungoid growth. From all his observations Prof. Frankland drew the following conclusions:—1. Potable water mixed with sewage, urine, albumen, and certain other matters, or brought into contact with animal charcoal, subsequently develops fungoid growth, and other organisms, when small quantities of sugar are dissolved in them and they are exposed to a summer temperature. 2. The germs of these organisms are present in the atmosphere, and every water contains them after momentary contact with the air. 3. The development of these germs cannot take place without the presence of phosphoric acid, or a phosphate or phosphorus in some form of combination. Water, however much contaminated, if free from phosphorus, does not produce them. A German philosopher has said "ohne Phosphor kein Gedanke." The above experiments warrant the alteration of this dictum to "ohne Phosphor gar kein Leben."

Anthropological Society January 31.—Dr. Charnock, President, in the chair. A paper was read by Mr. Joseph Kaines, on some of the Racial Aspects of Music. The author, in a very brief glance at the characters of the music of the various races of men on the globe, drew particular attention to a striking anthropological fact—namely, that the music of the people of the north-east of Europe, unlike that of all the rest, was pervaded by a settled melancholy. He sought to account for this phenomenon physically and psychically. He drew attention to the climatal and general physical conditions under which the peoples of the north-east of Europe live, and suggested that, in the constant war with Nature, and the endeavour to modify Nature's laws, they acquired a gravity, awe, and sadness, of which the peoples of the sunny south knew nothing, as their music showed, Nature having used them more kindly. The author contrasted the biographies (as well as the music) of the German and Italian composers, and showed that the men differed as widely; sadness and sorrow marking the one, brightness and gladness characterising the other. He commented upon the introspectiveness of the northern peoples, and the rapt attention and morbid analysis they give to the great problems of Life, Death, God, and Immortality; and stated that the contemplation of these and such sublime mysteries saddened and brightened by turns all their thoughts and impressions. It was curious to note that even the dance tunes and popular airs of the Germans, Norwegians, and Swiss, as has been remarked by Mr. H. F.

Chorley, the eminent musical critic, were in a minor key. "Joyousness," contined the author, "is a plant that does not flourish in the bleak north. It flowers and blossoms perennially in the south, because there the air is balmy and soft. There the skies are always bright, and beneath man's feet the earth is fruitful though untilled. There Nature uses her children kindly, and even "prepares for them a table in the wilderness.'" The author remarked incidenatlly that not music only, but the other arts of expression—architecture, sculpture, and the mythologies of the north of Europe—were imbued by the same melancholy spirit. He concluded by a few observations on the character of ancient Roman, modern Anglican, and dissenting Church music. The following gentlemen took part in the discussion: Mr. Mackenzie, Dr. Hyde Clarke, Mr. Bendir, Dr. Blake, Mr. Lewis, Mr. Wake, Captain Brine, Mr. W. R. Cooper, Mr. Quaritch, and the Chairman. The President announced that this was the last ordinary meeting of the Anthropological Society, an amalgamation with the Ethnological Society having been carried out by the delegates appointed for that purpose at the general meeting of this Society on January 17th. The new society was to be styled "The Anthropological Institute of Great Britain and Ireland."

Linnean Society, February 2.—Mr. G. Bentham, President, in the chair. The President announced the death of one of the corresponding members of the Society, Prof. Miquel, of Leyden; and also that the Council had agreed to recommend the election of Prof. O. Heer, of Zurich, to fill the vacancy in the list of foreign members caused by the death of Prof. Unger, of Vienna. —"Natural History of Deep-sea Soundings between Galle and Java," by Captain Chimmo. The ooze dredged up from a depth of 2,300 fathoms, where the temperature was found to be 35° F., consisted to the extent of 90 per cent. of organic matter, Foraminifera, chiefly Globigerinæ, together with Polycistinæ, with a few broken sponge-spicules. In the shallow water near Sumatra, the animal life had decreased to only about five per cent. of the ooze, the Globigerinæ having entirely disappeared. The water brought up from great depths was found to contain a large proportion of salts in solution, which crystallised out immediately on exposure to the air. Mr. Busk remarked on the great interest and importance of the observation of the low temperature of the deep water in a latitude within a few degrees of the equator, strongly confirming the conclusions as to a general circulation of the water between the equator and the poles drawn from similar observations in the Atlantic.

Victoria Philosophical Institute, January 30.—The Rev. J. H. Titcomb read a paper on "Archæology, with some of its Parallels and Contrasts;" it was a general review of the whole subject, and also showed how the resources of nature had been made use of by improving the arts. The discussion was carried on by the Chairman, Captain F. Petrie, Mr. V. Newton, the Rev. Mr. Heard, Mr. Shiffard, and Mr. Row.

EDINBURGH

Botanical Society, November 10, 1870.—Sir Walter Elliot, president, in the chair. The president delivered an opening address, in which he congratulated the Society on its continued prosperity, having now entered on its thirty-fifth year of existence. He reviewed the rise and progress of naturalists' field clubs in Britain, and concluded by giving short biographical notices of the members whom the Society had lost by death during the past year.—"Experiments on the Transpiration of Leaves," by Dr. W. R. M'Nab.—"On the Laws of Growth in Plants," by Col. T. B. Collinson.

December 8.—Mr. Alexander Buchan in the chair. The following communications were read:—"Botanical Excursions in July and August 1870, with pupils," by Prof. Balfour.—"Notice of some new and rare mosses collected on Ben Lawers," by Dr. Stirton. This was a continuation of a paper read by Dr. Stirton last session, recording the recent discovery of several new species of mosses on Ben Lawers, with notes as to place of growth, &c., of the rarer species found on that mountain.—"On the varieties of *Hieracium stoloniflorum* of Waldst. and Kit. at different seasons," by Prof. Balfour.—Prof. Dickson exhibited a plant of the Chinese primrose, having stamens and style of the same length (short), although in this species, as in the other dimorphic primroses, they are usually of different lengths. This form is interesting, inasmuch as in an abnormal cowslip, described some years ago by Mr. John Scott, the stamens and style, although of the same length, were both long.

BOOKS RECEIVED

ENGLISH.—The Text-book of Science; Algebra, and Trigonometry: W. N. Griffin (Longmans and Co.)—Strange Dwellings: Rev. J. G. Wood (Longmans and Co.).—The Sun: Ruler Fire, Light, and Life of the Planetary System: R. A Proctor (Longmans and Co).—The Schools for the People: G. Bartley (Bell and Daldy).

DIARY

THURSDAY, FEBRUARY 9.

ROYAL SOCIETY, at 8.30.—The Effect of Exercise on the Bodily Temperature: Dr. Allbutt.—Observations of the Eclipse at Oxford, Dec. 22, 1870: Prof. J. Phillips, F.R.S.—On the Problem of the In- and Circum-scribed Triangle: Prof. Cayley, F.R.S.—On the Unequal Distribution of Weight and Support in Ships, and its Effects in Still Water, in Waves, and in exceptional Positions on Shore: E. J. Reed, C.B.

THE EDUCATION OF CIVIL ENGINEERS

ATTENTION has been called to this important subject by a pamphlet recently issued by the Institution of Civil Engineers, containing a clear and well-digested account of the education and status of engineers at home and abroad. The pamphlet, however, is more remarkable for its omissions than for its contents, among which we find premisses warranting a conclusion or many conclusions concerning the education and position of the engineer in different countries. The documents which have been employed in its compilation have been collected, arranged, and issued, under the supervision of the Council of the Institution of Civil Engineers, a body most able to draw conclusions, and to give practical effect to any resolution they may adopt, and yet no conclusion whatever is drawn, and no resolution whatever is adopted. Perhaps, indeed, the Council consider that the education of engineers in England cannot be improved; this interpretation may easily be given to the short summary given of the English system, contained in the following passages:—

There is, further, in England no public provision for engineering education. Every candidate for the profession must get his technical, like his general education, as best he can; and this necessity has led to conditions of education peculiarly and essentially practical, such being the most direct and expeditious mode of getting into the way of practical employment.

The education of an engineer is, in fact, effected by a process analogous to that followed generally in trades, namely, by a simple course of apprenticeship, usually with a premium, to a practising engineer; during which the pupil is supposed, by taking part in the ordinary business routine, to become gradually familiar with the practical duties of the profession, so as at least to acquire competency to perform them alone, or, at least, after some further practical experience in a subordinate capacity.

It is not the custom in England to consider *theoretical* knowledge as absolutely essential. It is true that most considerate masters recommend that such knowledge should be acquired, and prefer such pupils as have in some degree attained it, and it is also true that intelligent and earnest-minded pupils often spontaneously devote themselves, both before and during their pupilage, to theoretical studies; but these cases, though happily much more frequent now than formerly, really amount only to voluntary departures from the general rule.

This thorough proficiency in practical matters tends largely to compensate for—in many cases to outweigh—the deficiency in theoretical attainments; and it is undoubtedly this, influenced in some degree by the natural self-reliance and practical common sense inherent in the English character, which has given such a high standing to the profession in this country. The *practical* education in England is perhaps the most perfect possible, if the opportunities obtained during the pupilage are ample, and the pupil properly avails himself of them.

In marked contrast with this language comes the summary of the description of foreign engineering education.

The education of foreign engineers is strongly contrasted with that in England in every particular. Practical training by apprenticeship is unknown; the education begins at the other end, namely, by the compulsory acquirement of a high degree of theoretical knowledge, under the direction, and generally at the expense, of the Government of the country. Partly with this, and partly afterwards, there is communicated a certain amount of information on practical matters; but this is imparted in a way differing much from the English plan, and probably with less efficient results.

Thus, while the English engineer is launched in his profession with the qualification of a considerable practical experience, but with perhaps little or no theoretical knowledge, the foreign one begins with a thorough foundation of principles, but with a limited course of practice; a deficiency, however, which tends to correct itself with time.

After a few paragraphs showing how these principles are worked out in various countries, we have a summary of suggestions made by engineers and others, without approval or condemnation. The body of the pamphlet consists of dry statistics, which would have been of greater value had not much of the matter been already published in various blue books; and at the end we find suggestions by individuals and extracts from published documents quoted, without any partiality for one rather than another.

It is very difficult to understand why the Council of the Institution has issued a document of this kind. Parents and guardians may find the list of schools and classes valuable, but neither the general public nor the engineers required information of the kind here given. Since the Paris Exhibition, we have been deluged with letters, pamphlets, and evidence as to foreign Polytechnic Schools. What we do require is some authoritative recommendation of one scheme rather than another for raising the standard of engineering education in England. The Council may plead in extenuation of this grievous omission that they are not a legislative body; that their decisions would bind no one, and that they have always disclaimed all responsibility for the opinions expressed in the engineering papers which they publish. If they take no higher view of their functions than this, they might well have abstained from publishing this dry collection of statistics. If, on the other hand, they really mean that the education of young engineers in England needs no improvement, it is a pity that the opinion is not stated in so many words.

The language used conveys a mild expression of paternal approval of the good boys who "spontaneously elevate themselves to theoretical studies," but we almost see the bland smile of compassion with which the successful Nestor regards the proud enthusiasts.

We have the list of colleges where these good boys may be (spontaneously) diligent, but not a word indicating that the number of institutions is insufficient; that the number of classes in the institutions is in defect or excess of the requirements; far less any recommendation that engineers should make attendance on science classes compulsory instead of voluntary. We have an excellent short account of the Whitworth Scholarships, but no word of approval, no hope expressed that the example set may be followed. There is no suggestion that any new technical chairs are required, such as those lately founded in Manchester and Edinburgh, and we can well imagine that when other colleges or patrons approach Government asking for assistance to supplement local efforts, the Treasury may point to this pamphlet and say, Surely if the leading engineers in the kingdom are satisfied, we cannot be justified in giving you the assistance you ask.

No preference is indicated for Mr. Scott Russell's tremendous scheme, of Great Eastern proportions, no condemnation is hinted of collegiate education for our Indian engineers. Engineering degrees meet neither favour nor contempt; the gods of the profession seem to live far removed from all this turmoil, and do not deign even to nod approval.

Seriously, it seems impossible that the Council of the Institution can rest satisfied with such a contribution to the cause of education as this barren pamphlet. It is their duty to take action; their recommendations would have no legal force, but great moral weight. Let them say whether they desire great Polytechnic Schools on the continental model. Not improbably public money will ere long be granted for some such. Let them approve or condemn the Indian College. Let them recommend engineers to compel the attendance of their pupils at suitable classes, and to refuse all students as apprentices who cannot show that they have received proper preliminary training. If proper classes do not now exist for the students, let them tell us where they are wanted and what they ought to be. Let them declare what the preliminary training of a pupil must be. Let them fix a practical value on the engineering degrees of those colleges which deserve such encouragement; or finally, if they will do none of these things, let them say, if they dare, that they are perfectly well satisfied with things as they are.

RECENT PETROGRAPHICAL LITERATURE
II.

Untersuchungen über die Mikroskopische Zusammensetzung und Structur der Basalt-Gesteine. Von Dr. F. Zirkel. (Bonn, 1870.)

Mikromineralogische Mittheilungen. Von Dr. F. Zirkel. Pp. 801. (Neues Jahrbuch für Mineralogie, 1870.)

Beiträge zur Petrographie der plutonischen Gesteine. Von Justus Roth. (Reprinted from the Transactions of the Royal Academy of Sciences of Berlin.)

Sur les Crystallites, études crystallogeniques. Par H. Vogelsang. (Archives Néerlandaises, 1870.)

Kritische Mikroskopisch-mineralogische Studien. Von H. Fischer. (Freiburg.)

Mikroskopische Unterscheidung der Mineralien aus der Augit, Amphibole und Biotit-gruppe. Von G. Tschermak. (Proceedings of the Vienna Academy of Sciences, 1869)

AMONG the Continental petrographers who have led the way in the recent reform and extension of this branch of science, none can claim a more prominent place than Dr. Zirkel. Although still a young man, he has held professorships successively at Lemberg and at Kiel, and we rejoice to hear from him that he has been selected to succeed the venerable Dr. Naumann at Leipzig. He is the author of many excellent mineralogical and petrographical papers, and of the best text-book of petrography which has yet been published. Especially has he distinguished himself by the zeal with which he has followed out the ideas first broadly sketched by Mr. Sorby, and has shown how absolutely indispensable is the application of the microscope to the study of the composition and history of rocks. His researches, while extending over the length and breadth of Germany, have not been confined to the Continent, but have been carried with characteristic enthusiasm even as far as the peaks of Arran, and the cliffs and glens of our north-western isles.

A few years ago he resolved to devote himself to a comprehensive study of the rocks to which the general name of basalt has been given. Though abundant chemical analyses had made the ultimate chemical constitution of these rocks well known, the mineralogical composition of them still remained rather vaguely defined. Their compactness and dark opaque hue made it difficult to investigate the separate mineral ingredients of which they consisted, and men were still speculating about the mineralogical nature of that part of basalt which is soluble in acid, when Dr. Zirkel set to work to collect specimens of basalt from every available locality, and to prepare thin transparent sections of them for examination with transmitted light under the microscope. The result of these investigations appears in the little volume now before us, which is appropriately dedicated to Mr. Sorby. In a brief introduction the author recounts the state of the question when he took it up. Having collected and prepared upwards of 300 sections of basalt from the most varied localities, he believes that he has obtained samples of at least the chief types of composition and structure among the basalts, and he now gives us this first instalment of his labour.

The first section of the volume treats of the microscopic structure and peculiarities of the minerals which enter as chief ingredients into the composition of basalt—augite, felspar, nepheline, leucite, olivine, magnetic iron, &c. This is an especially valuable part of the book, seeing that it furnishes materials for speculating both upon the conditions under which basalt was erupted, and on the various metamorphic changes which the rock as a whole and its component minerals in particular, undergo under the influence of percolating water and atmospheric weathering.

The second part deals with the general microscopic structure of basalt-rocks. The common notion regarding that structure has hitherto been that down to its minutest particles basalt is a crystalline rock, that its individual microscopic ingredients mutually impinge on each other, and that the difference between the structure, for example, of granite and basalt consists in little more than in the varying relative size of their component minerals. Prof. Zirkel, however, shows that this notion, which has been founded on mere deduction and not on direct observation, must be changed. He finds that in the majority of the specimens examined by him, there exists between the most minute ingredients a more or less abundant substance, not individualised into crystals, but amorphous, acting like a cement, sometimes glassy in character, sometimes half-glassy, owing to the appearance of hair-like particles, and sometimes completely dentrified so as to present a confused aggregate of darker or lighter minute granules, needles, hair, and crystals. He regards it as hardly possible to doubt that this glassy base in basalt is the residuum of the original *magma* out of which the recognisable minerals in the rock crystallised, and that it furnishes us with a new proof of the igneous origin of basalt.

In the next section the author proceeds to offer a new subdivision, and detailed descriptions of the basalts. He bases his classification upon the mineralogical composition of the rocks, as made known by microscopic analysis; and taking the non-ferruginous, colourless silicate as his guide, finds that the rocks hitherto classed under the general term basalt, group themselves naturally in three divisions: (1) the Felspar-basalts; (2) the Leucite-basalts; and (3) the Nepheline-basalts. All the three groups always contain augite and magnetic or titaniferous iron, and almost always olivine. So far as Dr. Zirkel's researches go, it appears that all our British basalt-rocks belong to the first or felspar group.

In the last few pages of his memoir the author adds some pertinent remarks on the hitherto vaguely defined series of rocks, which, as he remarks, under the various names of greenstone, trap, melaphyre, &c., play among the secondary and palæozic formations a part like that which is performed by the basalts in the tertiary formations. And here let us remark that in the chronological separation of igneous rocks made use of by our German fellow-workers, there is something eminently unsatisfactory. The term basalt is restricted by them to tertiary and post-tertiary rocks. But by what methods has the age of each rock been determined? No geologist who has ever had any experience in mapping a district of igneous rocks, can fail to realise how exceedingly difficult it sometimes is to decide upon the true age of such rocks. It is of course easy to say that all basalt is of tertiary or post-tertiary date, and, regarding this as an axiom, to look on every mass of basalt as of later origin than the secondary formations. But the axiom seems to us exceedingly doubtful. In Dr. Zirkel's memoir itself, we have basaltic rocks described which are not only certainly not tertiary, but are probably palæozoic. That igneous rocks have varied in the geological past is highly probable, but geologists are hardly yet in a position dogmatically to assert that no basalt was ever erupted before tertiary times. We cordially wish that our excellent friend Dr. Zirkel will take up the so-called melaphyres; and from what we have ourselves seen of the microscopic structure of the British examples, we shall be greatly surprised if he does not find that from these rocks to true basalt there is such an insensible gradation that no sharp line can be drawn between them. In the meanwhile he deserves the thanks and congratulations of all lovers of mineralogical geology for this admirable memoir on the basalts.

That Prof. Zirkel is still busy with his researches, is shown by the paper (second in the list at the head of this article) which appeared in a recent part of the *Neues Jahrbuch*, and in which he investigates the peculiarities in the minute structure of rock-forming minerals, and also of artificially-fused basalt and syenite.

If the limits of this journal and the patience of its readers permitted, a good deal ought to be said about Roth's most laborious work on the Petrography of the Plutonic Rocks. It is based on the analyses published from 1861 to 1868, which, given in full as an appendix, form half of the book. The word plutonic is used by the author in the sense of originating from igneous fusion, and he includes under it, not only igneous rocks commonly so called, but also gneiss, schist, and clay-slate. These, according to his view, are "the first crusts formed by the cooling of the earth's mass, not metamorphic, that is, not altered in various ways by dark, strange processes which appeared but once and never afterwards; although, indeed, these gneisses and schists, like other rocks, and even more than other rocks, by virtue of their antiquity and position, have undergone chemical changes." From this extract one may judge of Herr Roth's geology. He is a chemist rather than a geologist, and has gained deserved distinction for the great labour he has expended in the collection and discussion of analyses. In his present work, read as a memoir before the Berlin Academy of Sciences, he has amassed all the analyses he could find, which have appeared since the publication in 1861 of his *Gesteinsanalysen*, and has prefixed to them a discussion of the chemical composition of the various rock-species. As a work of reference in the chemical part of petrography, the book is of great value. Two important features are the analyses of decomposed rocks, and the account given of weathering.

Herr Voglesang is another ardent student of the microscopic structure of rocks. A few years ago he published a little work containing the most beautiful coloured illustrations of that structure which have yet appeared. In the present paper he describes under the name of *crystallites* the non-crystallised but yet more or less regularly grouped inorganic bodies which are found in crystals and rocks. As the paper, however, is to be followed by others, we reserve our notice of it for the present.

Professor Fischer's little pamphlet is a modest production, but one which could not have been prepared without a great deal of hard work. Finding that minerals, which to all outward appearance are simple and homogeneous, can yet be resolved by microscopic examination into as many as sometimes four distinct minerals, he has analysed by this method some sixty minerals, and publishes his results in the present paper, which should be in the hands of every petrographer.

Professor Tschermak's essay shows how by microscopical examination with polarised light, it is possible to distinguish augite and hornblende, even when minutely diffused through a rock. The paper is too important to be noticed at the end of this article, and we propose to return to it on a future occasion. ARCH. GEIKIE

GODMAN'S NATURAL HISTORY OF THE AZORES

Natural History of the Azores or Western Islands. By Frederick Ducane Godman, F.L.S., F.Z.S. (Van Voorst, 1870.)

SINCE the time when Mr. Darwin called attention to the peculiarities of the fauna and flora of the Galapagos in his "Journal of Researches," and showed in his "Origin of Species" how important were the lessons to be learnt from oceanic islands in general, the subject has had great attractions for naturalists, and much material has been collected for its elucidation. Mr. Wollaston's bulky volumes on the Coleoptera of Madeira, the Canaries, and the Cape de Verdes, are models of careful research; but Mr. Godman appears to be the first who has, after a personal exploration of one of these oceanic groups, endeavoured to collect all that is known of its natural productions, and published the result in a condensed and convenient form; and for so doing he deserves the thanks of all naturalists.

Oceanic islands, as defined by Mr. Darwin, are those smaller islands or groups which are more than 300 miles from the nearest continent, from which they are separated by deep sea. Their distinguishing character is, that they possess neither terrestrial mammals nor batrachians, and rarely any reptiles, and that a large proportion of their animal and vegetable inhabitants are quite peculiar to them, although allied to those of the nearest continent. Mr. Darwin was the first to maintain that all such islands had derived their organic productions by migrations from the adjacent land, rather than by union with it; and the facts and arguments he has adduced have convinced most naturalists of the justness of this view. It is powerfully supported by the fact that a connection can in almost every case be traced between the adaptability for migration of a group of animals or plants, and the amount of distinctness of the island species of that group from their allies elsewhere. Thus the land-shells of Madeira are the most peculiar of all its productions, the beetles and the plants less so, while the birds (some of which still come over annually from the continent) are almost all of European species.

The Azores, being about a thousand miles from the nearest coast of Europe, and being separated from it by a profoundly deep ocean, are pre-eminently oceanic islands, and an especial interest therefore attaches to their natural history. The facts, however, are different from what would have been expected, since some of the most striking peculiarities of such islands are far less manifested here than in others much nearer to the mainland; yet on that very account they offer a most convincing illustration of the truth of Mr. Darwin's view, since the cause of their deviation can be detected. Although so much farther from the mainland than the Galapagos or the Madeiras, they possess a far smaller proportion of endemic forms, either of animals or plants; about eighty or ninety per cent. being European species, except in the case of the land shells, where only forty per cent. are European. The explanation of this anomaly is to be found in the fact that the islands are situated in an exceptionally stormy region, gales of wind from every point of the compass being very frequent. As a result, strange land birds of many species appear after these storms; and we cannot doubt that winged insects and the seeds of plants also arrive, although these pass unnoticed. Thus, although these islands may have been isolated quite as long as the Madeiras, their productions being continually crossed by fresh arrivals from the Continent, have not been able to become as much modified by local influences. It is a most interesting fact that the Galapagos, whose productions are so highly peculiar, are situated in an exceptionally calm region. No emigrant land birds are known to visit them, and the result is, that the few wanderers who, by some strange accident reached their shores in the distant past (when circumstances may have been more conducive to such emigration), have been isolated ever since, and have thus had time to become modified into very distinct species.

Mr. Godman's volume consists of a brief account of his journey, of carefully compiled lists, with critical remarks on all the chief groups of terrestrial animals and plants, and of a well-written summary of results. He has obtained the assistance of Mr. Crotch for the beetles, of Mr. Tristram for the land shells, of Mr. H. C. Watson, who has given a most elaborate critical review of all that is known of the flowering plants and ferns, and of Mr. W. Mitten for the mosses and hepaticæ. There are two useful maps of the islands, and the relations of the several species to those of the Atlantic Islands, Europe, and America, are fully pointed out. In conclusion we may notice that there is a full index, that the type and arrangement are very clear, and that the book is issued with cut edges; and we may congratulate the author on having given us more useful matter in a small compass and in a convenient form, than is often to be found in works of much higher pretensions and at ten times the cost.

W.

OUR BOOK SHELF

Hardwicke's Science-Gossip. An Illustrated Medium of Interchange and Gossip for Students and Lovers of Nature. Edited by M. C. Cooke, M.A. (London: Hardwicke, 1871.)

THIS is the sixth volume of a magazine which may be said to fill in scientific literature very much the position which *Notes and Queries* takes in the literary world. The two resemble each other, indeed, in many particulars, and in none more than in the very unequal value which attaches to the articles contained in their pages. There can be no doubt that *Science-Gossip* has fulfilled its object in becoming "a medium of interchange and gossip;" the large number of writers who discuss a yet larger number of subjects in its columns give evidence of this.

As an example of the best of the papers in the present volume, we would refer to one entitled "The Towing-net," by Major Holland, which appeared in the September number, which is pleasantly written, well illustrated, and thoroughly correct in its details—although somewhat marred by an unfortunate mislettering of the engravings. It is evidently written from personal and practical experience, and is just the paper to awaken a taste for marine studies in any one who has time and opportunity to devote to them. Mr. Taylor's geological papers demand a word of praise; and a long account of a "formicary" in the November number will be read with interest. Mr. Harting and Mr. Robert Holland contribute respectively useful ornithological and botanical articles; and microscopy is well represented. In some of the papers, however, "gossip" appears to take precedence of "science," and thus we find a lady correspondent expressing her wonder "whether flowers suffer pain," and writing a paper of nearly two columns on "errors of the press;" which may be amusing, but certainly cannot by any effort of the imagination be called scientific. On the whole, however, the volume is a satisfactory one, the illustrations being especially well executed; and we have no doubt that it exercises a beneficial influence upon amateur naturalists. We should be glad to see the rule which obtains in *Notes and Queries*—that correspondents replying to queries should refer to volume and page where such questions are to be found—enforced by the editor of *Science-Gossip;* the convenience of reference to a correspondence on any particular subject would thus be much augmented.

Etudes faites dans la collection de l'Ecole des Mines sur des Fossiles noveaux ou mal connus. Premier fascicule. Mollusques Tertiaires. Par F. Bayan, &c. 4to., pp. 81, 10 plates. (Paris: F. Savy, 1870. London: Williams and Norgate.)

M. BAYAN, who occupies the office of Engineer of Bridges and Roads in connection with the Ecole des Mines, presents us in the work before us with descriptions of 47 genera and 106 species, illustrated by 139 well-executed figures of Fossil Tertiary Mollusca. The localities represented comprise the *Calcaire Grossier*, &c. (Eocene), of Longpont, St. Parres, Rilly, Roncā, Parnes, Aizy, Grignon, Anvers, Chaumont, and numerous other localities in France, Belgium, Italy, and Algeria. This is the author's second work, but out of the 106 species, upwards of 80 are christened by M. Bayan; which implies that either he has in the course of his researches come upon an unusually large number of new forms, or, not having been able to refer his new examples to the species already described by M. Deshayes and others, on account of their imperfect condition, he has preferred the easier method of giving them new names. Thus we find fifteen new Tertiary species of the genus *Cerithium* added to our already overburdened nomenclature, one half of which, at least, might have been referred to well-known species. This is all the more surprising as M. Deshayes' grand collection is now deposited in the Museum of the Ecole des Mines, besides numerous other well-known typical collections. The book is written and transferred to stone by a new auto-lithographic process, the result of which is that there are forty-seven more or less important errata given, which the reader must correct before he can use the book with safety. We are sorry to be unable to avoid what may appear a harsh criticism of M. Bayan's work, but those only know the labour which such monographs cause who require to use them as works of reference in the scientific determination of fossils. We are arrived at a period in palæozoology when we cannot be satisfied with merely getting a name to a fossil, but *we must have the right name*—that which expresses its identity with, or distinctness from, other nearly-allied forms obtained from other similar or different geological horizons around; so that as our work progresses we find we are helping to reconstruct a history of these old marine faunas, as a whole; not a series of disjointed essays. We want to see the work of Professors Beyrich and von Koenen in Germany, fitted in with that of M. Nyst in Belgium, and these with our countrymen Messrs. S. V. Wood and Frederick E. Edwards, joined to M. Deshayes' grand work on the Paris Basin; these again with Michelotti, Bellardi, and other Italian works, joined to Hörnes's great work on the Vienna Basin. By no other plan can we hope to arrive at a clear notion of the value of terms applied to geological horizons, and the names of the species by which they are characterised. H. W.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Scientific Instruction in Elementary Schools

WHAT is to be brought under the new Act in our elementary schools? The never-ending permutations and combinations of the three R.'s, attendant on Mr. Lowe's Revised Code of Education, will, doubtless, soon be at an end, or at least limited in number. What improvement will come? What encouragement will Government give to Science teaching? Under the Revised Code it well-nigh disappeared, or, if it lingered on in some few spots, became almost worthless, *per se*, owing to its necessarily disconnected and unsystematic nature. We say it *disappeared*, which implies that it once had a footing; it certainly had, and was to some considerable extent followed out in very many of our elementary schools. The Committee of Council encouraged it, not only by simply recognising it, which they have not done of late years, but by making special reduced rates to assist the teacher in experimental lessons. Ten or twelve years ago educational periodicals teemed with hints on the subject, and specimen lessons were frequently inserted at full length; books for the use of teachers were written by scientific men; the teaching of "common things," though not altogether scientific in its way, yet showed the general opinion of competent persons in the matter. Why has all this been allowed to die out? We know schools at the present time where the apparatus liberally granted by Government, in days long gone by, has been carefully locked up in the cabinet for years, waiting for more enlightened times to return. We do not say that the Committee of Council on Education has positively prohibited all scientific instruction in our elementary schools; of course, they have done no such thing directly, but, indirectly, they have prevented it:—(1) by not recognising it as formerly; (2) by discontinuing grants of apparatus; (3) by making the examination in reading, writing, and arithmetic so rigid as virtually to confine the attention of the master to these three subjects. The examination of the boys in these schools has, in fact, been proportionally much more severe than that of candidates for the Civil Service, and at the same time more so than that of the pupil teacher placed over them. Hence the teacher has hardly dared to venture on giving time to other subjects with the value of which he was at the same time well acquainted.

Our middle-class schools, as well as those of a still higher grade, are gradually becoming more and more convinced of the value of a scientific education, and we must not lose sight of it in our elementary schools. It is even more important there than in the others; there the "working man" receives his education, and if our artisans are to become really intelligent men, fitted to compete in their various branches of labour with their fellow workmen on the Continent, we must prepare them for it in early life, and they are to be found as children, not in such places as Eton, Harrow, or Marlborough, but in our National and British schools. Education, we are told, is to be extended and improved; how can it be better improved than by the increase of scientific instruction? Any elementary schoolmaster will tell us that the general education given in our schools now is far below what it was before Mr. Lowe introduced his changes. The three R's are, no doubt, better taught in many instances, but the intellectual powers of the children have not been drawn out and properly cultivated; we question whether in many cases they have not been stunted in their growth. The same three lessons morning and afternoon, day after day, for twelve months, until H. M. I. comes round again—what has it been to both teacher and children, but unwelcome drudgery? We do not think the Educational Department need feel the slightest apprehension that ordinary subjects of instruction would suffer by restoring the former state of affairs (though it is to be hoped they will go further than that); there can be no doubt that an extra hour or two during the week set apart for science lessons would be not only no loss of time but a positive gain in many respects, by enlarging the intellect of the children, and enabling them better both to apprehend and comprehend what is placed before them in other subjects. It is a great relief to teacher and children to turn for even half an hour a week from the usual monotonous course to some subject totally different, both in its nature and in the mode of treatment. We have seen the faces brighten up, and the eyes sparkle again at the preparations made for an experimental lesson in physical science, or for one in natural history.

We hope, then, to see a change for the better in this respect; we trust that the almost forgotten apparatus and the rolled up diagrams will once more see the light of day, and be restored to their legitimate use. As to the plans to be adopted, each teacher is the best judge, perhaps, in his own school; he knows how may hours per week can be spared from other subjects; but two branches of natural science at least should be taken up, one of which should be natural history, as at once the most interesting, the best adapted for cultivating the powers of close observation and discrimination, and as a study which can be most easily followed up by the pupil himself. But every boy in our elementary schools ought to have a fair knowledge of the laws of heat, of sound, of fluids, of health and ventilation, of mechanics; of the outlines of electricity, the chemistry of the commoner elements and their combinations, *e.g.* oxygen, hydrogen, nitrogen, carbonic acid, atmospheric air, coal gas, &c. &c.

The branches to be taught might vary in different localities, according to the nature and productions of the district, and the industrial occupations of the inhabitants, *e.g.*, in mining districts a certain amount of practical geology should be taught, together with a course of lessons on the minerals obtained there; in coal districts, the nature of the coal, the formations in which it is found, the principles of mining, the nature and properties of carbonic acid, light and heavy carburetted hydrogen, coal-gas, the principles of ventilation, especially in reference to mines; also to some extent lessons on flame and heat, the "Davy" lamp, and others used in the mines, &c. In manufacturing districts, similarly, a practica course on mechanics and steam might be followed out, and a certain amount of chemistry with regard to the operations performed such as bleaching. While in agricultural districts much might be done towards making the field labourer a more intelligent being than he is usually supposed to be, by giving lessons in agricultural chemistry, the art of draining, the laws of evaporation and condensation, the value of woodland, the construction of various implements used, &c. But in every locality lessons should be given in physiology, health, and ventilation, while natural history would everywhere form a not less pleasing than instructive alternative subject. The walls of every school, upper, middle, or elementary, should be covered with diagrams, and at the foot of these should be descriptive and explanatory notes.

As regards the teachers themselves, it may be left an open question as to whether they should be required to go through the ordeal of an examination in the subjects they take up, or whether it may be taken for granted that the mental discipline undergone for two years in the training college is sufficient to enable them to perfect themselves for the task. Those among them who have been at work for ten or fifteen years might probably feel indisposed to prepare again for examination; and we are ready to admit that if a man can bring up his pupils to the required standard, he may well be excused from any other test. At any rate it is to be hoped that the subject of scientific instruction in our elementary schools will receive that attention from Government which is due to it, and that having been once again taken up, it will never be allowed to fall into desuetude.

HENRY ULLYETT,
Hon. Sec. Folkestone Nat. Hist. Soc.
National School, Folkestone

The Prevalence of West Winds

IN NATURE of 29th September, 1870, there is an abstract of a paper read at the British Association by Mr. Laughton, maintaining that the preponderance of west over east winds over the entire globe is such as to point to a cosmical force of some kind, moving the atmosphere round the earth from west to east; and concluding "that the motive force for which we are seeking, is really the disturbing force of the attraction of the heavenly bodies."

The course here suggested, if it were operative at all, would act in the opposite direction to that required. The only possible effect of the attraction of the heavenly bodies on the atmosphere is an atmospheric tide, and the motion of a tide is necessarily from east to west, with the apparent diurnal motion of the heavens. But it is only when resisted that a tidal wave can give origin to currents, and it is scarcely probable that any tidal current can be formed in the atmosphere of sufficient force to blow a feather. I maintain the truth of the ordinary theory, that all winds originate in a disturbance of atmospheric equilibrium by unequal solar heating in different parts of the earth, but are changed in direction by the earth's rotation. This theory is quite consistent with the fact on which Mr. Laughton insists, that west winds preponderate over east winds. It is true that the mechanical effect of any wind whatever must be balanced by an equal mechanical effect in the opposite direction. Mr. Laughton appears to see that this would necessarily be the case if the ordinary theory of the winds is true, but he does not see how the compensation is effected. Were the winds all from the west, they would in an infinitesimal degree accelerate the earth's rotation; were they all from the east, they would in an infinitesimal degree retard it: and if either of these effects were proved to take place, the inference would be certain that the winds are set in motion by some other agency than unequal heating in different places; because, in virtue of the universally true principle of the "conservation of rotation," no such motive power could have any effect on the earth's rotation whatever.

The unbalanced effect of any wind on the earth's rotation will be due to the product of three factors, namely, the area covered by the wind, the east or west component of its force, and the radius of the parallel of latitude at the place. Mr. Laughton has probably overlooked the last-mentioned factor. It gives *leverage*. An east wind near the equator has more effect in retarding the rotation of the earth than a west wind of equal extent and force at a higher latitude has in accelerating it, just as a weight at the end of the long arm of a lever outweighs an equal weight at the end of the short arm. It is for this reason that the west winds, which are mostly in the higher latitudes, are of greater force, and probably cover a greater area than the east winds, which, under the name of the trade-winds, predominate near the equator.

Can Weather be Influenced by Artificial Means?

SOME remarks on this subject made by the Rev. R. B. Belcher before the Geological Section of the British Association (reported in the *Athenæum* of October 29), reopen a question of popular meteorology, which has not, perhaps, been sufficiently attended to, from an exact and scientific point of view. Such evidence on the subject, as is at present available to the public, is too general to have much claim to correctness of detail on points which require particular and *local* information; and I offer the following abstract of it principally in the hope that it may lead to further inquiry and observation.

The idea that large fires do, in some way, bring on rain, is very old; but it was, I believe, for the first time stated as a fact and explained on scientific grounds by the late Professor Espy. His theory is, that the heating of the air causes a rapidly ascending current, and that the moisture which air near the surface always contains, is thus carried into the upper regions of the atmosphere to be condensed and to fall as rain. In support of this view, he has given several instances in which rain did immediately follow the kindling of a fire, when no clouds had previously been visible, but in a problem of this nature, negative examples have more weight than positive; and it is necessary to admit that, though in some very remarkable instances rain has followed a large fire, in other instances, quite as remarkable, there is no notice of rain. It is, of course, difficult to speak with absolute certainty; it may almost always be said that a few drops have fallen, sufficient to bear out the truth of Espy's theory, but it seems to me that to establish it in its entirety, something more than this is necessary, and that an extraordinary fire ought to produce a very decided shower, if not a heavy downpour. Last summer, in July, a large fire raged for several days on the moorland and through the pine copses a few miles to the east of Wimborne-Minster. The weather was hot and dry. I was myself on a walking tour in that part of the country, and passed close by this fire, near the village of Longham, where it had been burning with great fury for a week. The farmers were all complaining of the long and excessive drought, and I can give my personal testimony to the fact that there was absolutely no rain. Similarly in the very dry summer of '68, the papers were for some weeks filled with accounts of fires raging fiercely in various parts of Wales and Scotland; but there was no word of any break in the drought. It is only by referring to exceptional and recent examples of this kind that we can feel any degree of certainty; wet weather and heavy rain are so common in this country, that under circumstances not very remarkable, they would scarcely be noticed; and these instances I have just mentioned show the necessity for caution before attributing to fire and consequent rain the relationship of cause and effect; and, as bearing directly on Espy's theory, I may add that there are no observations which would show that the rainfall in our large towns is greater than in the adjacent country; yet the thousands of fires in London, for example, must heat the air sufficiently to cause some ascensional tendency.

The evidence regarding the effect of violent explosions is in very much the same state of imperfection. Theoretically, we can admit that a violent shock may throw large masses of the lower air to a considerable height, so as to cause condensation of its vapour; and there are many instances which seem to support the conclusion that it does do so. The clearest on record are perhaps those mentioned by Dr. Darwin, in his Journal of Researches, where he describes how on several occasions a shower of rain fell, in the middle of the *dry* season, in Chili and other parts of South America, after an earthquake. After the earthquake in Peru, in the latter part of the year 1868, I went carefully through the published accounts, but found no mention of any similar showers. In our own climate, in which rain is not uncommon at any time of the year, the circumstances require to be examined into more critically, and the evidence afforded by them can never be quite so satisfactory. Whitaker's Almanack for last year, in the list of Remarkable Occurrences, &c., for 1869, mentions several serious explosions of powder mills, collieries, &c., but not one of them is followed by any notice of remarkable weather, storm, or rain; still, as one of these is the conflagration at Bordeaux on September 28th, which, as Mr. Belcher has pointed out, was followed by very heavy gales, both in the Bay of Biscay and in the English Channel, it is likely enough that heavy weather following some of the other accidents may have been omitted, or have been insufficient to call for special mention in such a general list.

The effect of great battles, again, has always been a favourite theme amongst popular meteorologists; but in regard to this also there is the same uncertainty. Several battles and bombardments have been followed by storms; but, on the other hand, several have not. The general opinion amongst naval men is that heavy firing beats down the wind and produces a calm; and it is tolerably certain that this is frequently the case, more especially if the wind is light. Whether it does or not, the sudden irruption of millions of cubic feet of gas into the lowest strata of the atmosphere and within a very limited area, must have a tendency to cause disturbance, a tendency increased by the undulatory movement due to the noise of the guns. The battle of Trafalgar (October 21st) was fought in a very light westerly breeze, which, towards the afternoon, almost entirely died away. During the night the wind gradually freshened, and by noon the next day blew very hard. Lord Collingwood in his despatch, dated the 22nd, says it had "blown a gale of wind ever since the action;" but that this is merely a general way of speaking is seen by a reference to the logs of the various ships of the fleet. (Despatches of Lord Nelson, vol. vii., pp. 159, *et seq.*) A westerly gale, on the coast of Portugal or Spain, is not such an unusual occurrence in the end of October, as to compel us to attribute one to a battle which took place twenty hours before it came on. Again, the battle of St. Vincent, of the Nile, Rodney's action off St. Domingo, and many others, do not seem to have been followed by any interruption to the usual fine weather. Quatre-bras was followed by heavy rain; but the night after Waterloo was fine, and the bright moonlight is specially mentioned as advantageous to the pursuers; and though Mr. Belcher speaks of rain as having set in in the east of France during the present campaign, I have not seen any notice of its following the battles of Gravelotte or Sedan, so as to be clearly referable to them.

What appears to me the only explanation of the apparent contradictions in the evidence is this; that large fires, explosions, battles, and earthquakes, do tend to cause atmospheric disturbance, and especially, to induce a fall of rain; but that for the tendency to produce effect, it is necessary that other conditions should be suitable; that rain does not follow, unless the lower air contain a great deal of moisture; and that therefore the ascensional movement does not reach to a height such as we might at first be led to conceive; that, in fact, the height is for the most part very trifling. With regard to storms said to have been caused by some of these agencies, the evidence is still more unsatisfactory; and, in our present ignorance of the cause of storms generally, is quite insufficient to compel us to attribute any one particular gale, extending probably over a wide area, to some very limited and comparatively insignificant disturbance.

J. K. LAUGHTON

Natural Science at Cambridge

THE rejoinder in your last number (p. 287) to my inquiries is rather ingenious than ingenuous. "The Writer of the Article in Question" vouchsafes no answer to my very plain questions (p. 264), but is kind enough, instead of justifying his own statement, to propound sundry suggestions, surmises, and what not. I simply asked for confirmation of a certain assertion. This he avoids giving, and, though I regret the cause, I do not wonder at it. Some persons may think it would have been better taste to have acknowledged that the assertion was unfounded. Perhaps your correspondent is of another opinion; if so, I do not wish to interfere with him. I have only to remark that substantially he admits the force of the doubt I expressed by now modifying his previous statement as to "most of the colleges" into "some colleges"—perhaps "one college" would have been nearer the mark, but I will let that pass, hoping that when he again writes on the subject, events may have proved him to be a true prophet.

Cambridge, Feb. 10 M. A.

Glass Globes

IN consequence of the letter of Col. Greenwood, which appeared in NATURE of the 1st December last (No. 57, p. 87), I wrote to Dr. G. O. Sars, of Christiania, who is the Inspector of Sea-fisheries in Norway, for information on the subject. In his reply, just received, he says he was not aware that such globes were used as net floats in any other country than Norway, and that until quite recently they had been used there in the great cod fisheries at Lofoten only. At Söndmör, in Christiansand, they had begun to come into use in 1869, but by no means generally. He has no doubt that the floats washed ashore in Shetland and the Hebrides came from Lofoten; but he remarks that their course in a south-westerly direction is quite contrary to what might be expected from the action of the equatorial current; and he suggests that before reaching our northern coasts the floats made a very long course, having been first carried northwards until they got within the range of the Polar stream, by which they may have been carried southwards along the coast of Greenland, and so at last coming within the influence of the Gulf-stream, they were carried eastward across the Atlantic, and thence drifted by south-westerly winds to their destination. He adds that the fact of their having been found on the *west* coast of the Isle of Lewis seems to confirm this hypothesis.

Feb. 13 J. GWYN JEFFREYS

P.S. on another subject. The correspondents in recent numbers of NATURE do not appear to have been aware of Dr. Carpenter's and my remarks in the *Athenæum* of the 22nd of October last on the hypothesis of the Cretaceous formation being continued or not continued up the present time.

The Primary Colours

HERE is another proof that violet is the third primary. Prof. Tyndall, with that sagacity which results from the right use of his imagination, has given us a reason for the blue colour of the sky. It is probably the true reason, and it proves that blue is not a primary colour. The smallest light-waves are those of the extreme violet. These, therefore, are the waves which will be reflected in greatest proportion by the minute particles of foreign matter in the air. Why is not the sky violet then, instead of blue? Plainly, because although violet predominates in the reflected light, there is also a small proportion of green and a still smaller proportion of red. Suppose the ratios to be 1 red, 3 green, 6 violet, and suppose the ratios for white light to be 1 red, 2 green, 4 violet. Then, the light of the sky will be white *plus* 1 green, 2 violet, which is blue. In Professor Tyndall's experiment on the decomposition of sulphurous acid gas by a beam from the electric lamp, he tells us that, as the particles of the sulphur cloud grow larger, the colour changes from pale blue to deeper blue, and then to whitish blue and white.

No colour but blue makes its appearance, because there is always some green and red, as well as violet; and always a surplus of green *over* red, more than enough for white light.

Leicester, Jan. 28 FREDERICK T. MOTT

Yellow

IT would seem to me that the great difficulty of conceiving yellow as a compound colour is the brightness or lightness of yellow, as compared with its components. In the spectrum, we have the maximum of light in the yellow, and it is against our experience to put two dark colours together and form one light one, as, for example, to put the red and green together and form yellow. But there is just the same difficulty in the production of white light from all the colours of the spectrum, for we regard white as lighter than any of the colours, even than yellow. This, however, is a mental fallacy, and if once exposed, seems to me to do away with the difficulty of conceiving white as made up of a series of colours. Our ideas of colours and tints are derived from our own experience, and we produce tints by precisely the opposite method to that of nature. Nature's method of painting a blade of grass is, to throw on it all the colours of the spectrum, and afterwards pick out those which shall have a *residue* of green. The artist's method is to see what colours will produce green and then lay those on. I do not think it too much to say that all colours are merely tints of white—that, for example, yellow is really yellowish white, green, greenish white, and so on. If we take two cards, one green, the other red, and hold them so that the light is properly reflected from the one on to the other, the cards do not appear black but white. If the red and green were pure colours, the cards should of course appear black, for the light from the green card would be totally absorbed by the red card, and similarly with the red card. The white cannot be produced by a combination of the red and green, but by the extinction on one card of the green that gives the greenish white, and on the other of the red which gives the reddish white. That yellow is but little different from white is well illustrated in the beautiful experiment of Newton's of synthesising the colours of the spectrum by reflection from seven moveable mirrors. With the mirrors placed at equal distances from each other, the spot of compound light is not white but yellow, that is to say, it is yellowish white, the colours lost between the mirrors being just those necessary to bring out the full white.

C. J. WOODWARD

Meteor

A FINE meteor was seen here to-night at about 9.10 P.M.; it was described to me as starting from near θ Orionis, and proceeding towards a point a little north of γ Eridani, when it was lost behind a belt of cloud. J. M. WILSON

Rugby, Feb. 13

Snake Bites

IN NATURE of Dec. 22 I notice a note extracted from the *Pall Mall Gazette*, giving a return of the excessive number of deaths which take place annually in the Bengal Presidency, from the effects of snake-bite. That 11,416 persons die from this cause alone, "and that no efficacious means are adopted to check its ravages," are very startling announcements, and strike me as being well worth the attention of the readers of NATURE.

Upwards of a year ago Dr. Fayrer recorded an elaborate series of experiments on snake poison, in the *Indian Medical Gazette*, from which he concludes "that if an animal, and probably a man, be fairly bitten by a fresh and vigorous cobra or daboia, it or he will inevitably succumb unless some immediate or direct method of arresting the entering of the poison into the circulation be practised." This direct method is to apply ligatures and cauterisation; for, says the same authority, "to conceive of an antidote, in the true sense of the term, to snake poison, one must imagine a substance so subtle as to follow, overtake, and neutralise the venom in the blood, or that shall have the power of counteracting and neutralising the deadly influence it has exerted on the vital forces." I remember reading some time ago of another doctor in India or Australia, who had tried ammonia as an antidote, but I cannot recollect with what result. It seems to me, however, that this real antidote has still to be found: and cauterisation, to prove effectual, must follow the course of the poison, which it cannot do; nor, indeed, is it possible for it to do much more than burn the walls of the wound, so it is not to be wondered at if some of those subjected to this powerful treatment do not recover.

I have long thought that the best cure for snake-bite would be powerful suction, applied to the wound by means of an instrument made for the purpose, and similar in principle to a boy's sucker. This would draw off a considerable quantity of the blood in the neighbourhood of the wound, and by so doing wash the poison out before it. Above the wound there might be a ligature applied, but sufficiently distant from it to ensure that the blood in the small vessels between the wound and ligature be competent to wash out the poison.

Where such an instrument is not at hand, and the assistance of a second party can be obtained, he might tie a ligature above the wound, and suck the latter with his mouth for a considerable time, spitting out all the saliva and blood which accumulates. It would be advisable, too, to make the wound a little larger before commencing to suck, with a sharp knife or otherwise, in order that the greater flow of blood may the better discharge the poison. The operation of sucking the poison into the mouth need not be feared, for even although a small portion of it were swallowed, it could do no harm. I believe I am correct in stating that a quantity of poison which will prove fatal on entering the circulation, would have no injurious effect when taken into the stomach. Where the bite is in such a part of the body that the party bitten can easily suck it himself, then he ought to do so: but unfortunately this is seldom the case, it usually being the lower extremities which are attacked.

In support of this method, I may say that I read, two or three years ago, an account of how the bites of snakes were counteracted in a woody portion of South America. The writer said when any one was bitten—and there were one or two almost daily—he was sure to die in thirty minutes to one hour afterwards if his wound was not immediately sucked. There, however, in order to make quite certain that the poison, when sucked out of the wound, would have no injurious effect on the sucker, the latter filled his mouth with olive oil before applying it to the wound: and I imagine this would be a sure precaution, for it provides a plentiful supply of matter for the poison to diffuse in, without interfering much with the absorbents of the mouth. The result of this writer's experience was that the bitten person seldom, if ever, died; and he who sucked the wound never felt an injurious effect.

This subject seems so important that I have ventured to address you at this length upon it, in the hope of drawing from some of your correspondents further details concerning antidotes and methods of curing snake-bite. T. L. PATTERSON

The Cretaceous Period

IN NATURE of Jan. 19, a letter appeared from Prof. Wyville Thomson defending the expressions, "we are still living in *the* Cretaceous epoch," "*the* chalk is being formed at present in the bed of the Atlantic." When first this announcement was made, it was followed up by various strong comments implying that the similarity of the Atlantic mud to the chalk in lithological character, and in many of the imbedded organisms * "would seem to unsettle much that has generally been accredited to geological science," would, in fact, revolutionise geological classification.

As these unfortunate expressions are again put forward, notwithstanding the protest of our most distinguished geologists,† Sir Roderick Murchison and Sir Charles Lyell,‡ it may be useful to consider what the question at issue really is. Simply stated, it is this: Have we sufficient evidence for drawing one of our strongest lines at the base of the tertiary deposits, and saying that it marks the commencement of a new epoch or period?§

In grouping the rocks, we have been obliged frequently to adopt an arbitrary classification. The thickness will not furnish the necessary tests, as accumulation is more rapid at one time and place than another. Lithological character will not do alone, as a bed often passes both vertically and horizontally into one quite different. The organic remains will not do alone, as the fauna migrated and re-migrated to suitable areas when favourable conditions recurred.

But sometimes we have the commencement of a new period well defined by seeing that the group of deposits which form the record of it rest unconformably on an older formation, which has been in part at least heaved up, denuded, and used to form the new series. At the bottom of this newer series we must infer a considerable break—a portion of unrepresented time.‖ This time may be represented elsewhere, but we have a point in time well marked by the first grain of the new deposit laid upon the older denuded rocks.

So we are quite safe in saying that there had been a considerable lapse of time, and that new conditions prevailed over large areas when the Cambrian was laid unconformably upon the Laurentian, when the Upper Old Red was laid unconformably on the Lower Old Red and Silurian, when the Permian was laid unconformably on the Carboniferous and more ancient rocks.

Probably deposition went on longer over one area than another—very likely deposition has never in the earth's true geological history been entirely arrested, so that the connecting deposits between any two formations and intermediate forms of life may possibly still be preserved under the depths of ocean or on the vast still unexplored continents. It would be of course difficult under such circumstances to identify in a series of more or less continuous deposits the base line we have so well marked elsewhere by visible unconformity; and this difficulty occurs in the older rocks, as, for instance, in the case of the base of the Upper Old Red or Carboniferous in South Wales, of the Permian when the Rotheliegende is present, and many others, but this arises from our want of data. We might fairly hope that if we could find the continuous deposits after enormous intervals represented by known unconformities, we should read a wonderful story, and know, for instance, more clearly by what variation of forms and invasion of stronger life from adjoining areas we are left at the end of a long period with an ammonite instead of a goniatite, or a nautilus instead of either.

Now, to return to the particular case under notice. Have we at the bottom of the Tertiary formations evidence of a break so large, of a lapse of unrepresented time so long, of a change in conditions over large areas so great that, we are justified in saying that this is a convenient place to draw one of our strong lines?

* Carpenter, Lecture Royal Institution, Ap. 1869.
† Pres. Add. Geog. Sect. Brit. Assoc., Liverpool, 1870.
‡ Students' Elements of Geology, 1871.
§ See also an able article by Mr. Green, *Geol. Mag.*, Jan. 1870.
‖ See Ramsay, Pres. Add. Geol. Soc., 1863-4.

The overlap and irregular occurrence of the Tertiary on various parts * of the Cretaceous deposits, the immense banks of flints containing Cretaceous fossils in the Tertiary beds, point to an enormous amount of change and denudation between the consolidation of the Cretaceous and accumulation of the Tertiary deposits. This is accompanied by an almost entire break in the higher forms of life.† It is true that the researches of Dr. Carpenter and his colleagues have brought to light many forms which have survived from the Cretaceous to our own time; but these discoveries are only of the same kind as the discovery in recent times of the genus Lingula, or of forms allied to Encrinites. When we trace back to a remote antiquity ferns and other plants not very unlike those of our own day, Crustacea differing but little from our King Crab, Paludinas hardly distinguishable from recent forms—that does not throw doubt upon the useful grouping of the rocks from carboniferous to recent times.

Species are continually being found common to two beds known to be separated by enormous intervals of time. Upon this fact Barrande founded his theory of the Colonies. But the classification into Mesozoic and Tertiary depends upon evidence that cannot be shaken by the discovery of a few more forms common to the two. The wonder always was that the break in life was so complete as it appeared to be at the close of the Cretaceous period, and the deep-sea dredging expeditions confirm what was *a priori* almost a necessary inference, that deep-sea conditions prevailed somewhere during the whole of the period from the Cretaceous age to our own, and that some forms of life have not been destroyed or developed into anything else during that period; but that is a very different thing from saying that there is not sufficient reason for holding that the base of the Tertiaries marks the commencement of a new epoch.

T. M'K. HUGHES

* See Lyell, Student's Elements of Geol., pp. 258, 261, where attention is called to higher cretaceous beds than those on which the Tertiaries rest in England.

† Lyell, Op. cit. p. 256.

Insulation of St. Michael's Mount, Cornwall

HAVING read Mr. Peacock's letter in your publication of the 2nd inst., I beg, through the same medium, to show that his reasons for supposing "the mount could not have been an island in 1086" are groundless.

He begins by giving the measurement of "Domesday Book," date 1086, of "the Land of St. Michael," and afterwards writes as follows:—

"There is an entire absence in 'Domesday Book' of any mention of island or islands on any of the coasts of Cornwall. . . . In short, the mount could not have been an island in 1086, because it contained at least eight times as much land as it does at present, probably connecting it with the main land, from which it is even now only one-third of a mile distant. . . . The present area of the mount is only thirty acres, so that there are 210 acres missing . . . since 1086; and in 1099, thirteen years after, we have a record of a catastrophe which would fully account for the loss"—that being the great irruption of the sea in 1099, as recorded in the Anglo-Saxon Chronicle.

When yonr correspondent quoted the measurement of "The Land of St. Michael" above referred to, he evidently imagined St. Michael's Mount, with the Church or Monastery on its summit, to have been like a nobleman's seat in the midst of a large park, with the sea at a great distance from the centre—and all this to have been comprehended in "The Land of St. Michael." The fact, however, is that in 1086 the Mount was, as it still is, a rock about five furlongs in circumference at its base, and insulated by every tide, whilst the two parishes on the mainland nearest to it—viz., those of St Hilary and Perran-Uthnoe (which may be identical with "The Land of St. Michael"), were then holden by the Church or Monastery of the Mount."‡ As the mount, however, is now almost universally allowed to be the *Iktin* of Diodorus Siculus, we may be sure that it was long before the commencement of the Christian era insulated daily as it is at present. I have written very fully on this subject in my work already referred to, published in 1862, and also in a paper printed in the Transactions of the Plymouth Institution for 1867-68 (pp. 17-37), in both of which I have exposed the error of all the translators of Diodorus in calling the mount *Iktis* instead of *Iktin*, and have also shown that the Mount, which was called in the Cornish language *Bre*-tin ("Tin-*Mount*") as well as *Ik*-tin ("Tin-*Port*"), has given its name, not only to *Mount's Bay*, but probably also to the whole of *Britain*.

R. EDMONDS

Plymouth, February

P.S.—I had written the above before I saw Mr. H. Michell Whitley's letter in your last number, which states that instead of "*Keiwal holds the Church of St. Michael*," as Mr. Peacock has translated the passage in Domesday Book (p. 2), it should have been "*The Church of St. Michael holds Keiwal*" (or Treuthal, as it is also called on p. 11), which is the name of a manor in the parish of St. Hilary. This confirms what I have above written, although I have adopted a different way of disproving Mr. Peacock's theory.

‡ See my "Land's End District—its Antiquities and Natural History," p. 166.

Aurora Borealis

A FINE Aurora was seen last night, or this morning, from 1 to 3 A.M. It first appeared as a *transverse* band from N.E. to S.W., and passed in that course far South of the Zenith, or between Arcturus and Mars. Subsequently it spread laterally and upwards; presently radiated from near the Zenith to all azimuths; and at 2.30 A.M. some of the rays N.E. were strongly pink.

In the spectroscope, the usual green line was gloriously bright. I saw it first, with a hand spectroscope, in the darkened light of the rough glass panels of a stair door. There were also faint lines more refrangible over the regions of E, b, and F. Rather to my astonishment, I was totally unable to see a red line, even when looking at rays abundantly pink to the naked eye. This was a disappointment, to say the least of it, because I had prepared, and had in the lower part of the field of view, red chemical lines to compare with anything red that should appear in the Aurora; and I had seen the red line perfectly well in the fine auroras of last autumn, but then I had no such checks on its place.

However, my spectroscope is still a very rough, home-made affair; and I am living in hopes of something better when Government supplies this Observatory at last with its long-desired, long-delayed equatorial.

Royal Observatory, Edinburgh, Feb. 13 C. P. S.

*THE THEORY OF GLACIAL MOTION**

MR. CROLL'S papers on Ocean Currents are a powerful application of the modern theory of heat and force, to show the fallacy of Captain Maury's explanation of the causes of oceanic circulation. They also discuss other matters of great interest, but as the concluding part is not yet published, we shall say no more about them at present, but that they well deserve careful study.

The other paper is a criticism of the Rev. Canon Moseley's supposed proof that glaciers do not descend by the force of gravity, and of the arguments of Messrs. Ball and Matthews on the other side. It will be remembered, that Canon Moseley determined by experiment the "shearing" force of ice, that is, the force required to fracture it by parallel pressure. A plug of ice of known cross-section is fitted into a hole through two smooth boards, and the force required to break the ice by sliding the boards over each other is the "shearing" force. Increasing this in proportion to the dimensions of a glacier, or of any large portion of one, it was calculated that the force required to cause the different parts of a glacier to slide over each other (as they must do in descending a valley of constantly varying form and size) was at least thirty times greater than the force of gravity on a slope such as glaciers easily descend. Canon Moseley came to the conclusion that expansion and contraction of the ice by heat and cold was the moving power; and the fact that the glaciers move slower by night than by day, and in winter than in summer, was supposed to prove conclusively that heat is the cause of motion.

Mr. Croll believes that Canon Moseley has demonstrated that gravity alone does not cause glaciers to descend, but he completely demolishes the theory of contraction and expansion. He admits that heat aids the motion, but maintains that it does so by acting on the molecules of

* "On Ocean Currents." By James Croll, of the Geological Survey of Scotland (3 parts). "On the Cause of the Motion of Glaciers." By the same author (Extracted from the *Philosophical Magazine* of 1870.)

the ice, which it loosens momentarily from their mutual cohesion, and allows to be re-arranged under the influence of gravity. Heat, he says, is the *condition*, gravity the *cause* of the motion which takes place, molecule by molecule rather than in masses. It seems very doubtful, however, if this theory is more tenable than the one it is intended to supersede. If heat entering the glacier loosens the molecules in its passage and enables them to move insensibly into new positions, it is difficult to understand what causes the numerous longitudinal and transverse fissures of a glacier, the production of which is often attended by loud reports, and which indicate movements of masses, not of molecules. And how could molecular motion lead to that heavy grinding of the ice over its bed, which scores and wears down the hardest rocks, and whitens great rivers with the finely triturated mud?

None of the opponents of Canon Moseley have noticed what seems to the present writer to be a radical fallacy in his argument about "shearing force." He assumes that, whatever the bulk or weight of the glacier, or of any portion of it to which the formula of the shearing force may be applied, the whole mass shears at once by the action of gravity on the same mass, and does not recognise the possibility of one portion of a glacier acting by its weight to shear another and much smaller portion. But this must inevitably occur; for, owing to the excessive irregularity of the bed in which every glacier moves, the mass must be every where in varying states of tension and compression, and must contain at each instant certain lines and planes of least resistance, the extent of which lines and surfaces may be very small compared with the dimensions of the glacier itself. At any moment, therefore, the whole descending weight of a portion of the glacier containing perhaps thousands of cubic yards of ice, may act so as to cause the shearing of a few superficial feet where the tension is greatest. This being effected, a partial equilibrium is produced there; but the points or surfaces of greatest tension are shifted, and another small shear or fracture occurs; and by this process and the continued regelation of fractured surfaces brought into contact, it may easily be seen that the glacier as a whole would be gradually moulded to its bed, which it would descend as surely as if it were a viscous mass. Another source of motion not taken into account either by Canon Moseley or Mr. Croll is the irregular melting away of the under surface of the glacier by terrestrial heat, which would often form unsupported hollows till a fracture occurred, and every such fracture must result in a downward motion of a portion of the glacier. The observed difference of the rate of motion between winter and summer, day and night, is more probably due to the different quantities of water which descend the crevasses into the bed of the glacier at those periods, than to any direct action of the heat. It is well known that in the higher portions of a glacier the supply of water from melting snow diminishes during the night, as it does in a still greater degree during the winter; and the large quantity of water that flows beneath every glacier in the summer must greatly assist its motion, both by melting away its lower surface, and by, to some extent, buoying it up.

Mr. Matthews's important experiment of the bar of ice which gradually curved by its own weight, should be tried again in an atmosphere kept at the freezing point. This would settle the question whether heat is an essential condition for the curvature or motion of ice by gravitation; but so far as the facts lead us at present, the arguments of Canon Moseley and Mr. Croll by no means *prove* that glaciers do not descend by the force of gravity alone.

ALFRED R. WALLACE

[The publication of this article has been delayed. It was in our hands before the appearance of Mr. Ball's paper in the *Philosophical Magazine* for February, where a view almost identical with Mr. Wallace's is ably advocated.—ED.]

AN ACCOUNT OF THE ECLIPSE AS SEEN FROM VILLASMUNDA BY AN UNSCIENTIFIC OBSERVER

THOSE set in authority over the branch of the Eclipse Expedition stationed at Agosta having decided against depending only upon observations to be made from the Observatory there, deputed Mr. Ranyard to proceed to another point upon the line of totality, and selected me as his coadjutor. Accordingly we set off, accompanied by Jarvis and Burgoyne, two of Colonel Porter's Sappers, at half-past nine in the morning of the eventful day; and, after driving some eight miles inland, we attained about eleven o'clock a point which appeared to my companion to present advantages for our object. Leaving the road, we went into the middle of a field of springing oats, on the highest point of a rocky ridge at an elevation of 600ft. above sea level, and of 520ft. above the *glacis* of Fort Agosta, where were posted the rest of our friends. The spot which Mr. Ranyard selected as the most suitable lay about a hundred

FIG. 1.
A our position; B the sun; C C, C C the lines of cloud; D the road to Agosta.

yards from a roadside farmhouse, called Casa Vecchia, upon the property of that friend of Science, the Marchese di Sangiuliano, and about two miles distant from the village of Villasmunda. A keen wind was blowing with considerable violence from the north-west, and the situation we had chosen being exposed to its full fury, we at first felt very uneasy with regard to our probable success, for we feared every moment that the telescope would be overturned and injured. A happy thought, however, soon extricated us from our dilemma. Causing our luckless coachman (who wept true Sicilian tears over the imaginary danger to his springless vehicle) to drive it, in the cause of Science, over the rock-sprinkled field, we utilised our carriage as a temporary shelter for the precious instrument, and were ready some time before the first contact took place. During the time occupied in perfecting the necessary preliminaries, I noted the position and the structure of the cloud-banks which were instilling into our minds feelings of the keenest anxiety. We were standing in the centre of what I may describe as a comparatively cloudless longitudinal "slit" in the sky, which was otherwise completely covered; so that, while over our heads the sun was shining brightly, its refulgence obscured only occasionally by light, fleecy, flying clouds; to our front and rear were lying parallel lines of heavily-banked "cumuli-strata" running from south-west outh-east. Perhaps the accompanying rough diagram (Fig. 1) may serve to illustrate their position in relation to our own.

I also set down the following readings of the barometer and thermometer (wind N.N.W.):—

	At first contact.			Five minutes before totality.	At 2.20 P.M.
Barometer	28·65	28·79	28·88	28·80	28·75

At first contact.

Thermometer in shade	56°
" in sun exposed to wind	54°
" in sun	58°

Immediately after totality.

Thermometer in sun exposed to wind	55°

Two minutes before the commencement of totality, the clouds behind us, and those in front of us, were black and threateningly lowering, as if a thunderstorm were imminent. Etna, which lay well in our view to the N.N.W., was clothed to its very base with a shroud of the most sombre clouds, while as the seconds flew by the temperature fell sensibly lower and lower.

To the S., and S.W. also, the sky was filled by a strange, steamy, V-shaped (the point of the V being near the earth), filmy mist, through which the sun showed such a feeble and uncertain light, as to give me cause for fear lest our observations should be brought to an abrupt and resultless termination by the total disappearance of the sun behind this curious veil. *Immediately* before totality commenced, a dark vaporous shadow glided very swiftly up over the heavens from the westward, or a little south of west, and, as it came on towards us, seemed to swallow up the earth, leaving it dark in its rear, until at the moment of totality it reached the sun. As it drew near him, a herd of oxen feeding behind us, with one or two exceptions, lay down. With the beginning of totality the air was colder than ever, and for about one minute's space, not more, there fell a small thin rain, which I fancy must have been the result of the condensation of the steamy mist which I have a little while ago described. Of totality itself, as a spectacle, I am almost afraid to speak. To endeavour to describe the inconceivable grandeur of the sight would be a hopeless task. I can only say that nothing will ever efface it from my memory. But if I cannot hope to give you any idea of the sublimity of the scene, at any rate I will do my best to state simply the appearances which I saw. Round the dark moon gleamed the luminous circle of the corona, shining with about half the radiance of an English sun upon a winter's afternoon; while there streamed forth from it in eight directions as many sets of brilliant rays. These "sets" of rays were composed of four sets in the position of a Greek cross, as in Fig. 2; with a St. Andrew's cross, as in Fig. 3, placed upon it, forming something similar to Fig. 4, Fig. 3 extending only about half as far as Fig. 2, which reached as far outwards as the apparent diameter of the sun.

I described the phenomenon to Mr. Ranyard as having struck me by its resemblance to the "glory" round the heads of statues of saints in Roman Catholic shrines.

Jarvis and Burgoyne also made sketches of the "rays" separately, and without consultation with me or with each other, at my request. The similarity of the three is striking. Jarvis described the rays as resembling "the pipes of an organ."

FIG. 2.

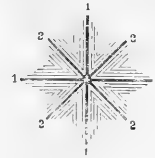

FIG 4.

FIG. 3.

As the moon passed off from the sun's face, and for some seconds after the contact had wholly ceased, the clouds in the S.E. were suffused with deep red copper colours, which gradually faded away as the sun regained his power. During totality I made the following observations (according to Mr. Ranyard's previous request) with a Nicol's prism with Savart's bands, in the use of which instrument Mr. Ranyard had instructed me, and with which I had constantly practised during our week's preliminary residence in camp at Agosta; viz., I determined the polarisation of the sky at two points: (1) high up on the sky to the S.E. of the sun; (2) under the sun; and at both these points I found the plane of polarisation to be vertical. Totality ceased while I was taking a third observation.

Before concluding these imperfect remarks, which I have only ventured to make public because I thought that they might be of some interest, from the fact of my having had the good fortune to be one of the very few who obtained a perfectly clear and distinct view of the Eclipse during totality, I should like to bear my testimony to the great kindness of Colonel Porter, R.E., in placing all the resources at his command at the service of our party, and to his care of our creature comforts during our ten days' "dwelling in tents" under his charge. It is but just also to mention the zeal and alacrity displayed by his party of Sappers, and their intelligence in mastering the details of duties which were certainly new to them. Nor will it be considered out of place if, in conclusion, I thank the authorities of Agosta, and the Italian astronomers of distinction who did so much, not only by giving us every assistance in their power to render our stay at Agosta so successful, but also by their hospitable attentions to make it as enjoyable as possible. For my own part I can only say that I shall always look back with feelings of pleasure to the Sicilian Eclipse Expedition of 1870.

HENRY SAMUELSON

NOTES

THE Royal Commission on Scientific Instruction and the Advancement of Science is now in full work. This week they meet three times, and last week they met twice.

IT has been announced at the Royal Geographical Society that Livingstone has arrived at Ujiji on his return journey.

THE Hunterian Oration has been delivered this year by Sir W. Fergusson, who *inter alia*, according to the *Times* report, "playfully referred to the suggestion of a distinguished philosopher, whose views appeared in the columns of the *Times* last autumn, that when the microscope did not seem to give satisfaction in minute research, imagination might be substituted; and pointed out that this style of philosophy was not new, for it had been put into Hamlet's mouth by Shakespeare:—

Imperial Cæsar, dead, and turned to clay,
Might stop a hole to keep the wind away."

MR. J. C. BUCKMASTER has been appointed by Her Majesty's Commissioners to deliver an address on the value of the International Exhibition, with its bearing on industrial instruction, designed particularly for the working classes in all the large towns of the country which express a desire to hear it.

SCIENCE has derived many wrinkles from the siege of Paris, and we now learn from the correspondent of the *Daily Telegraph* that all the galleries of the Louvre are filled with sacks of earth to protect the interior from shells; and the damp and comparative warmth of the last few days have provoked active vegetation, so that the bags are covered with grass and weeds; each window is converted into a lively and promising garden. If the arrangement is left undisturbed much longer, we shall have flower beds there. This is certainly a novel kind of window-gardening, which we have no desire to see introduced into this country.

M. STEENAEKERS is about to issue a report on aëronautical ascents which took place during the siege of Paris. Individual reports are asked from aëronauts, but, unfortunately, very few of them are in a position to give a correct idea of their impressions, being mostly sailors of the Royal Navy.

AMONGST the learned men who escaped from Paris in a balloon we must cite M. d'Almeida, author of a treatise on Physics. He escaped on the 17th of December, at one o'clock in the morning, in the "Guttemberg," with four or five other persons. The "Guttemberg" was despatched a few minutes after the "Parmentier," which carried three persons and a bag of letters, and fell within Prussian lines. M. d'Almeida landed at Sanson, eight miles from thence, but he has not been heard of since that time, and it is to be feared that he was taken prisoner with his companions and sent to some German fortress.

THE French Government had amalgamated the post-office and telegraphs during the siege of Paris, under the management of M. Steenaekers, for the whole of France except the besieged capital. This reform was inaugurated in imitation of the English system under the pressure of circumstances. But a retrograde step was taken a few days ago, and two different services have been created as formerly. It is to be hoped that so unscientific a measure will soon be cancelled.

FRENCH *savants* do not appear to be successful politicians under universal suffrage. Amongst more than 2,000 citizens who offered themselves as candidates to the Parisian electors, we notice only a few members of the French Académie des Sciences. The only names who have come under our notice are M. Sainte-Claire Deville (we do not know if it is Henri or Charles), and M. Nelaton, the physician who cured Garibaldi's wound. M. Berthelot was also a candidate, but he does not belong to the Académie des Sciences. The Académie Française was more successful, as Michelet, Victor Hugo, Henri Martin, Thiers, Jules Favre, and many others, were chosen.

WE learn from the *British Medical Journal* that the distinguished ophthalmologist, Dr. Liebreich, has just passed an examination and been admitted a member of the Royal College of Surgeons. It is stated that he will be invited to accept the ophthalmic chair of St. Thomas's Hospital.

THE death is announced of Dr. Sheridan Muspratt, F.R.S., the well-known analytical chemist of Liverpool, and author of a Dictionary of Chemistry.

THE following is the list of officers and council of the Royal Microscopical Society for the current year:—President: W. K. Parker, F.R.S. Vice-Presidents: Chas. Brooke, F.R.S., J. E. Gray, F.R.S., J. Millar, F. H. Wendham. Treasurer: Richard Mestayer. Secretaries: Henry J. Slack, Jabez Hogg. Council: R. Braithwaite, M.D., John Berney, James Glaisher, F.R.S., W. J. Gray, M.D., Henry Lawson, M.D., Henry Lee, Jas. Murie, M.D., G.W. Royston Pigott, M.D., J. W. Stephenson, Chas. Stewart, Chas. Tyler, T. C. White. Assistant Secretary: Walter W. Reeves.

MR. A. R. WALLACE has printed his Anniversary Address, delivered before the Entomological Society on Jan. 23rd. After referring to the loss Entomology has sustained during the past year by the death of J. T. Lacordaire and A. H. Haliday, and to the publication of Mr. Crotch's papers on the Genera of Coleoptera studied chronologically, McLachlan's Catalogue of British Neuroptera, Dr. A. S. Packard's Guide to the Study of Insects, and some other works of the year, the greater part of the address is occupied by a critique on Mr. Andrew Murray's important paper "On the Geographical Relations of the chief Coleopterous Faunæ." Of Mr. Murray's division of the Coleoptera of the world into three grand stirpes or races—the Indo-African, the Brazilian, and the Microtypal—the first comprehending all the characteristic forms of the eastern tropics, the second all those of tropical America, and the third those of the temperate regions of the whole world, not excluding even America—Mr. Wallace remarks that the two first will probably be generally accepted, while the third group, as of equal value to the others, will be as generally rejected. Mr. Murray's theory, derived from the geographical distribution of the Coleoptera, that the whole of the Atlantic Islands, from the Azores to the Cape de Verdes, and even to St. Helena, are portions of a vast submerged continent connected with Southern Europe, is combated by Mr. Wallace as far as the Madeira group is concerned, while he considers there is more to be said in favour of their connection with one another at some remote period.

THE third session of the Ladies' Educational Association of London is considered a successful one. The number of tickets issued has been:—for English Literature, 56; English Language, 40; Psychology and Logic, 46; French Literature, 39; French Language, 20; Experimental Physics, 25; Chemistry, 10; Total, 236, against 292 last year. The falling off is almost entirely in the class of English Literature, in which 104 tickets were issued last year, a decrease of 48 in the present session. The attendance is reported as regular. Lecture associations of a similar kind for ladies have also been established in the northern and eastern districts of the metropolis.

THE Annual Report of the Canadian Natural History Society states that the recent dredgings of Mr. Whiteaves have added many facts to our knowledge of the creatures which inhabit Canadian seas. The marine mollusca have been carefully monographed, and instead of 60 or 70 species, we now know of nearly 130, the number having been thus nearly doubled. The careful identification of the inhabitants of the deep sea, in addition to its zoological importance, will do much to illustrate the conditions under which the Canadian post-tertiary deposits have been accumulated.

WE have on our table a number of important papers referring to the Colony of Victoria, prepared by Mr. W. H. Archer, Registrar-general to the Colony, and published by authority of the Colonial Government: viz. Patents and Patentees from 1854 to 1866, Abstracts of Specifications of Patents applied for from 1854 to 1866 Ac. to Bu., and Indexes to Patents and Patentees for 1867 and 1868. Also Reports of the Mining Surveyors and Registrars for the quarter ending Sept. 30th, 1870, Report on the present condition of the Geological Survey of the Colony, and Abstracts of English and Colonial Patent Specifications relating to the Preservation of Food, &c., compiled from original documents, by Mr. W. H. Archer. We would call especial attention to the last as a well-arranged epitome of very useful information.

DR. M. T. MASTERS and Dr. J. H. Gilbert reprint from the *Proceedings of the Royal Horticultural Society* "Reports of Experiments made in the Gardens of the Society at Chiswick in 1869 on the Influence of various Manures on different Species of

Plants." The experiments afford striking illustrations of the varying powers of accumulation and assimilation possessed by plants belonging to different families, to different genera of the same family, and even to different species of the same genus, under the same external conditions of supply in soil and atmosphere, indicating, as the authors think, not only very varying ranges of root-collection, but also quantitatively varying functional characters, both of the feeders and the elaborating organs. It is expected that results of considerable practical value to agriculturists will be obtained from the second series of experiments which were conducted during 1870. The Royal Horticultura Society appears to be applying its resources to a very useful end in the carrying out of these investigations.

WE have received from Mr. F. Bradley, of Chicago, a pamphlet, entitled "Northern Lights, Shooting Stars, and other Meteoric Phenomena proved to be not of modern origin," in which he explains several well-known Biblical figures by the supposition of an acquaintance on the part of the writers with the phenomena of the Aurora Borealis, and combats the views of a recent writer that the alleged occurrence of the Aurora within the last three centuries for the first time, is a sign of the approaching end of all things.

THE great difficulty which has been experienced by farmers during the present winter in procuring sufficient food for their cattle may have the effect of directing attention to fresh substitutes for the ordinary winter keep. Turnips and Swedes have been a complete failure throughout a large breadth of the country, and the hay crop has been generally so deficient that many agriculturists have been already brought to the verge of ruin. In the Argentine Republic, as is well known, vast herds of cattle are reared upon the natural grasses of the pampas, or upon the lucerne which grows there in great abundance, but in the province of Catamarca both man and beast depend for support mainly upon the leaf and fruit of the algarrobo. It provides their principal stock of food during the winter months, and is said to be exceedingly nutritious. The algarrobo (*Hymenæa Courbaril-Jetaiba*) is indigenous to the country, and its fruit is gathered annually and stored with much care. The long pods are pounded in a wooden mortar, and the residuum is then passed through a sieve, and the meal converted into circular cakes, which, after having been dried in the sun, are fit for use. In this state it is called "patay," and is exported as a bread-stuff into other districts of the Republic, in some of which it forms the exclusive food of the people. Its merits as a means for fattening cattle are also thoroughly appreciated, and it might be a great boon to our farmers, if the Acclimatisation Society would ascertain whether the algarrobo might not be introduced into this country with advantage. The tree grows to a height of forty feet, with wide-spread branches, and a rather slender stem, and flourishes best upon a dry soil.

CONSIDERABLE discusion took place in the *Times* last autumn as to whether acorns were suitable for employment as food for cattle; and the evidence adduced certainly favoured a negative view. Dr. Robert Brown, however, tells us that those produced in California by several species of oak form an important article of food. "The acorns of California are mostly large, and the trees in general produce abundantly, though in some years there is a great scarcity, and much misery ensues among the poorer natives. The acorns are gathered by the squaws, and are preserved in various methods. The most common plan is to build a basket with twigs and rushes in an oak tree and keep the acorns there. The acorns are prepared for eating by grinding them and boiling them with water into a thick paste, or by baking them into bread. The oven is a hole in the ground about eighteen nches cubic. Red-hot stones are placed in the bottom, a little dry sand or loam is placed over them, and next comes a layer of dry leaves. The dough or paste is poured into the hole until it is two or three inches deep; then comes another layer of leaves, more sand, red-hot stones, and finally dirt. At the end of five or six hours the oven has cooled down, and the bread is taken out, an irregular mass, nearly black in colour, not at all agreeable to the eye or to the palate, and mixed with leaves and dirt."

THE Proceedings of the Somersetshire Archæological and Natural History Society for 1868-69, just published, consists almost entirely of papers which would come under the first head. The only ones bearing directly on Natural Science are "On the Geology of the Mendips," by Mr. C. Moore, and "On the Rodentia of the Somerset Caves," by Mr. W. A. Sanford. Is it necessary that Reports of the Proceedings of Local Societies should be published at so high a price as practically to take them out of the reach of the general public?

MR. F. ABBOTT has reprinted a paper read at the meeting of the Royal Society of Tasmania, Oct. 11, 1870, "On the Sun and its Office in the Universe."

WE recently referred to Mr. Townend Glover's paper "On the Food and Habits of Beetles," issued in the Report of the Commissioner of Agriculture for Washington. A work, similar in style, but more comprehensive, has been published by the Board of Agriculture for the State of Missouri, which has secured "an appropriation for this purpose from the Legislature of the State." This "First Annual Report on the noxious, beneficial, and other Insects of the State of Missouri" is furnished by Mr. Charles V. Riley, State Entomologist, and from its plain descriptions, and rough, yet accurate, woodcuts, seems admirably adapted to fulfil the purpose for which it is published—that of giving the farmer a knowledge of his insect friends and foes which he may turn to practical account.

THE *Geraniaceæ*, taken as a whole, are by no means noted for their economic properties. In Tasmania, however, a form of the common *Geranium dissectum* having a thick rootstock is employed by the aborigines, who are in the habit of digging up the large, fleshy roots and roasting them for food. About Launceston it is called "native carrot," and is common throughout the colony. The typical form of *G. dissectum* is generally diffused over the temperate regions of the northern hemisphere in th Old World, where it is annual. In the Eastern United States a biennial or annual form, *G. carolinianum*, takes its place, the typical *G. dissectum* being only known as an introduced weed; although connecting links between the two may readily be detected. West of the Rocky Mountains the stock often appears to be perennial, and it cannot then be distinguished from some of the Australian forms.

WE may call attention to an interesting paper, reported in our present number, by Mr. Cecil Smith, read before the Somersetshire Natural History Society, on the relations of the Great Bustard, which has once more visited England during this severe winter. Mr. Smith removes the bird from the Rasores, among which it was placed by Mr. Yarrell, and restores it to the position assigned it by Cuvier, among the Grallatores, near to the Plovers.

THE question of killing deadly snakes at Government expense in India is again under discussion. The Government is losing its subjects at the rate of above a hundred a day, or 40,000 a year by snake bites, but it fears losing rupees in the crippled state of its treasury. The last enforcement of the law was under Mr. Commissioner Plowden, many years ago in the Bancorah district, one of the smallest portions of the Burdwan division. Deadly snakes were brought in at the rate of some 1,200 a day, and although the scale was only from threepence to sixpence apiece, in about a couple of months 10,000*l.* was drawn out of the treasury, and the Government ordered the snake crusade to be stopped.

MOUNT WASHINGTON IN WINTER

By the kindness of an American friend, we have been favoured with a Boston newspaper containing an account of an important meteorological experiment which has recently been tried in America with the greatest success; we refer to the establishment of a winter observatory on the summit of Mount Washington at an elevation of something like 10,000 feet above sea-level.

Everybody knows that Mount Washington, in New Hampshire, is visited by thousands of persons in the summer months, and that its climate corresponds better with that of Labrador or Greenland than with that of New England. In the winter universal desolation reigns there; not even the proprietors of the hotels upon the summit venturing from their snug quarters below to learn what events are transpiring upon the icy cone. The aborigines declared it to be sure death if anyone climbed the mountain—since it was the sanctuary of divinities who would not suffer their abode to be scanned with impunity. Their successors first adventurously found the summit—then erected rude places for shelter, and finally constructed a carriage road and railway, so that even the most feeble persons could view the broad panorama. But these visits were confined to the warmer months, with a few rare exceptions.

Twelve years ago Profs. C. H. Hitchcock and J. H. Huntington, independently of each other, conceived the project of spending the winter upon the summit of Mount Washington, but the project did not take shape till the organisation of the Geological Survey of New Hampshire in 1868. They found it impossible to make the necessary preparations for occupying the summit during the winter of 1868, chiefly for want of a dwelling. Hence they sought for a less elevated summit, where a single winter's experience might prepare the way for the greater adventure. That peak was Mooselauke, nearly 5,000 feet above the ocean. The lessee, D. G. Marsh, of Warren, N.H., obligingly placed his house at the service of Prof. Huntington and his comrade, A. F. Clough, of Warren, photographer. Their three months' occupation of Mooselauke was full of adventure, and experiences were acquired of the highest importance. The scientific results were important, disclosing the knowledge of violent winds there accurately measured, and remarkable forms of frost-work never before described or photographed. Attention was called to this mountain, and a carriage road became a necessity, which was constructed in the following summer.

In the month of September, 1869, the Mount Washington Railway Company generously tendered the use of their depôt upon the summit to this meteorological party during the winter; and the necessary supplies were immediately purchased and forwarded to the mountain. The enterprise, though of a meteorological character, has been adopted by the Geological Survey of the State, while the expense has been assumed by the State geologist, relying upon a sympathising public to provide the funds by subscription.

Congress recently appropriated funds for the establishment of a "Bureau of Telegrams and Reports for the Benefit of Commerce." After some correspondence with the efficient officer in charge of this bureau, General Myer ordered an insulated telegraph wire with suitable instruments to be sent to the mountain, in order to facilitate the transmission of the meteorological reports, both to the public and to the office of the bureau in Washington. The wire has been laid, and the summit is now in telegraphic communication with the world. And the chief signal officer also detailed for special service upon the mountain an experienced telegrapher and meteorologist, Sergeant Theodore Smith, of the U.S. Army.

The photographers of the expedition are Mr. A. F. Clough, of Warren, and Mr. Howard A. Kimball, of Concord, N.H. The latter gentleman spent much time in providing photographic material for the mountain, and in soliciting subscriptions. Their views of the peculiar phenomena of the mountain will soon be exhibited.

Thus the party consists of six persons: Prof. Hitchcock, whose office in Hanover, N.H., is connected by telegraph with the summit; Prof. Huntington and Mr. Nelson, observers; Messrs. Clough and Kimball, photographers; and Sergeant Smith, telegrapher and observer. All of them are not upon the mountain at the same time. They relieve each other to a considerable extent in the work, and the public will be kept informed of their whereabouts.

From the dépôt of the Mount Washington Railway in summer, the ascent on foot, if a person is accustomed to walking, is comparatively easy. Although the ties are three feet apart, and there is a rise of a foot in three part of the way, yet a person with muscles strong from exercise, can walk to the very summit of the mountain without sitting down to rest. But suppose it is winter. The snow has accumulated to a considerable depths even in the ties, but then it is no great hindrance; should it, however, be attempted a second time, you will find that the snow that was compressed beneath the feet has changed to ice, and the oval forms give a still less secure footing; if it is thawing, and the ice is almost ready to slip off as you tread upon it, every one will see that upon a trestle thirty feet high walking is *somewhat* dangerous, and to walk down is a feat from which even a most expert acrobat would shrink. If at the dépôt we take snow shoes, we can walk with comparative ease half way up, and then the snow is so compact that they are no longer needed, and as there are few irregularities in the surface the walking is better than in summer.

Above the limit of the trees the railway is covered with ice of every fantastic shape, and the framework of the Gulf tank is now so ornamented that one can hardly believe that it is the rude structure seen in summer. The Lizzie Bourne Monument, which one is accustomed to see only a rough pile of stones, is now an object of architectural beauty such as no sculptor can carve from marble. Immediately above the monument the timber trestles are completely covered with deposits of frozen mist extending two or three feet horizontally from the timber on which the track is laid, and every piece of timber which forms the trestle is ornamented with beautiful forms of frost-work, deposited in graceful curves as the wind sweeps through the trestle.

On the summit, the buildings, the piles of rock and stones, so rough in summer, are now completely covered with frost, while the snow fills the spaces between the jagged rocks. On the sides of the buildings towards the north-west the frost has accumulated, so that now it is more than a foot in thickness. The frost-work on the dépôt, while it has everywhere the same general appearance, the points show exactly the direction of the wind as it came into every nook and corner of the building. The frost on the braces and timbers that extend outward seems like one triangular mass, and on the chains it is often two feet in diameter. The correspondent then adds:—

"Although I was on the mountain for ten days in October, yet I did not go to stay permanently until November 12. It was expected that some of the party would be ready to go with me, but as they were not I went alone, and it was not till the last day of November that anyone came, so that I had the house and the mountain all to myself for nearly three weeks. During the greater part of November the weather was remarkably pleasant. On the 15th, all day long, and far into the night, the clouds were below the summit of the mountain, and most of the time they covered the entire country. At times only the very highest point of Mount Washington was above the clouds. It reminded me forcibly of the time, during the Champlain period, when the whole of New England, except Mount Washington, was beneath the waves of the ocean. As the masses of clouds came over Adams and Jefferson, I looked until I almost persuaded myself that there were immense icebergs coming from the uplifted frozen North, but the illusion vanished as the summits appeared above the clouds. But what was remarkable is that the next day was pleasant.

"During the last two weeks in November, the average of the thermometer was 16°. The wind was north-west nearly the whole time. The weather was generally very mild, and the number of clear days was much greater than the average."

We may add to this interesting account that the daily telegrams received from the mountain have been full of interest. A temperature of 40° below zero has not been uncommon, and we may well hope that the efforts of the solitary watchers on the inclement mountain-top will tend to advance the science of which they are such devoted students.

SCIENCE IN VICTORIA

THOSE who have read the Marquis de Beauvoir's "Voyage round the World" will recollect the high praise with which he speaks of Sir Redmond Barry's prolonged and continuous efforts for the advancement of Science in Victoria. His latest good deed in this direction is the aid which he has afforded in the establishment of a School of Mines at Ballarat, which, to use his own words, may now be regarded as "an accomplished fact," since "everything connected with its establishment and maintenance has been thoroughly debated and determined on." The prospectus of the Institution states that "the object sought to be obtained is the combination of the highest scientific with the most practical training for all men engaged in the enterprise of mining in its various branches — whether so engaged as mining managers, engineers, surveyors, mechanists, working miners, directors or promoters of companies;" and, as there is every reason to believe that the school will be supported by the Government, by the several mining boards, and by the general public, we may hope to see it in actual operation in a few months.

We have not space to give a sketch of Sir Redmond Barry's excellent address, further than to remark that he points out the general bearings of chemistry, electricity, geology, steam, &c., on the progress of mining; and we must content ourselves with the following extract relating to the progress of Science in Australia:—

"We are not," he observes, "even in our time, satisfied to import the discoveries of others, and to invite the man of science and the skilled artisan to direct their operations. Australia can point with a modest satisfaction to the invention of Osborne in photo-lithography, and the test for blood by Dr. Day;* to the cure for snake-bites by Professor Halford; to the method of removing pyrites, that inveterate enemy of the metallurgist, as well as the native alloys, from gold, and toughening the metal by the use of chlorine gas, by Mr. Miller of the Sydney Mint; to the scientific preservation of the meat of our redundant flocks and herds, so largely exported; and also to many others, mention of which would delay us too long."

THE CONTRACTION OF THE EARTH†

THE phenomena, which were ably presented by the distinguished geologist, Mr. Lesley, to the National Academy of Sciences, and which seem to demonstrate that the outer shell of the earth has sensibly shrunk, in some directions at least, since its original formation, naturally invite the attention of physicists to the possible causes of such a result. The most obvious cause of the shrinking of the earth is its cooling. But to shrink two per cent. linearly, which is the amount deduced by Mr. Lesley from the observed geological phenomena, involves a probable cooling of the whole earth of not less than two thousand degrees centigrade, which would require that its original temperature should be higher than would be consistent with the solidity of these shrunk strata.

Another source of change of form, which would produce shrinkages in different directions in different parts of the earth, is to be found in the diminution of oblateness arising from the diminished velocity of rotation upon the axis. Such diminution of the velocity of rotation has several years ago been shown by Mr. Ferrel to be caused by the action of the moon in producing the tides; this is, therefore, a true cause, and it is only necessary to examine how great its amount can be under any circumstances. This is all which is proposed in the present investigation, and the application to facts is reserved for geologists.

It is sufficient, for the present object, to regard the earth as homogeneous. Under this condition Laplace has shown that the time of the earth's rotation could not be less than about one-tenth of a day, which corresponds to a ratio of the axis of the equator to that of the pole, equal to 2·7197, and an equatorial circumference 94 per cent. greater than the present one. Such is then the amount of shrinking which might have taken place, if any cause could be assigned capable of producing so great a reduction of the earth's velocity. The whole surface of the earth would have been about 130 per cent. larger than at present.

But the only cause at present known which would produce a sensible reduction of the earth's velocity is the lunar action upon the tides. But in this mutual action between the moon and the earth, the common rotation area of the earth and moon must remain unchanged. The question then arises, How great a reduction of the rotation area of the earth would have passed into that of the moon? In this inquiry it may be assumed that the moon revolves in a circular orbit in the plane of the earth's equator.

Now the moon's rotation area is 3·716 times the earth's. But if, in the origin, it had revolved just in contact with this earth, its rotation area would not have been less than 0·480 times the earth's, so that it could not have absorbed a rotation area from the earth greater than 3·236 times the earth's present rotation area, and therefore the earth's rotation area could never have exceeded 4·236 times that which it has at present. But, with the maximum velocity of rotation given by Laplace, the earth's rotation area would have been $37\frac{1}{2}$ times greater than at present. It can never, therefore, have been reduced to so great an extent by the moon's action on the tides. But since, when the oblateness is small, the rotation area is nearly proportional to the velocity; and the excess of the square of the equatorial above that of the polar axis is nearly proportional to the square of the velocity, this excess may have been originally nearly eighteen times as great as at present, or about $15\frac{1}{2}$ per cent. of the square of the polar axis. This would correspond to a figure of the earth in which the equatorial radius would have been about $2\frac{1}{2}$ per cent. greater than at present; so that it is sufficient to account for the observed phenomenon.

This peculiar form of shrinkage would produce the highest mountains at the equator, and the tendency of the mountain ranges would then be to assume the direction of the meridian. But nearer the poles the mountains would be less elevated, and would rather tend towards the direction of the parallels of latitude.

It is, next, expedient to consider the mechanical question of the loss of living force in the case of the moon's action upon the waters of the earth, and its effect upon their different motions. In this connection there are problems worthy of the attention of geometers; such as the relative motions of bodies rotating above the same vertical axis, towards which they are drawn by weights, and acting upon each other through the friction on the axis. For one of the bodies a rotating wheel may be substituted. There is also the case of two planets revolving about a primary, and acting upon each other through some form of friction.

In this way it will be seen that the planet or satellite once formed is constantly removed from the primary, and that planets tend to approach each other. It is interesting to consider whether this may not be one of the actual problems of nature.

B. PEIRCE

* A full account of Dr. Day's remarkable colour-tests for blood and pus may be found in Dr. Richardson's Report on Toxicology in the last number of the *Medico-Chirurgical Review*.—ED.

SOCIETIES AND ACADEMIES

London

Royal Society, February 9.—"Abstract of Paper on the Effect of Exercise upon the Bodily Temperature." By Dr. T. Clifford Allbutt. The object of the author in carrying out the experiments recorded in the present paper was to inquire whether the regulating power of the organism held good under great variations of muscular exertion. For this purpose he made frequent daily examinations of his own temperatures during a short walking tour in Switzerland, and found that the effect of continuous muscular exertion upon himself was to sharpen the curve of daily variation, the culmination being one or two-tenths higher than usual, and the evening fall coming on more rapidly and somewhat earlier. Charts of the daily temperatures were handed in with the paper. The author made reference also to some observations of M. Lortet, which differed from his own. These observations, which did not come into Dr. Clifford Allbutt's hands until his own experiments were partially completed, were adduced by M. Lortet to prove that the human body was very defective in regulating power under the demands of the combustion needed to supply the force expended in muscular exertion. Dr. Clifford Allbutt's results were very decidedly opposed to those of M. Lortet; for only on two occasions did he note the depressions of temperature which M. Lortet regards as constant. It would seem, however, that the body is more or less liable to such depressions when engaged in muscular exertion; but the cause of them is very obscure. Of the two low temperatures noted by the author, one occurred during a very easy ascent of lower slopes, and the second was observed during a descent. The author thinks that they may be due to some accidental deficiency in combustion, and inquires whether the capacity of the chest in different individuals may account for the varying influence of muscular effort upon them, and perhaps for the earlier or later sense of fatigue. The sphygmographic tracings added by M. Lortet to his temperature charts seemed to show a great inadequacy of circulation.—"Observations of the Eclipse at Oxford, December 22, 1870." By John Phillips, F.R.S.

Geological Society, January 25.—Mr. Joseph Prestwich, F.R.S., President, in the chair. Richard Atkinson Peacock, of St. Helier's, Jersey; Arthur W. Waters, Davos Plaz, Canton of Grisons; R. Koma, of University College, London; and Ransom Franklin Humiston, M.A., Professor of Chemistry in Cleveland University, U.S., were elected Fellows of the Society. The following communications were read: 1. "On the Physical Relations of the New Red Marl, Rhætic beds, and Lower Lias," by Prof. A. C. Ramsay, LL.D., F.R.S., F.G.S. The author commenced by stating that there is a perfect physical gradation between the New Red Marl and the Rhætic beds. He considered that the New Red Sandstone and Marl were formed in inland waters, the latter in a salt lake, and regarded the abundance of oxide of iron in them as favourable to this view. The fossil footprints occurring in them were evidence that there was no tide in the water. The author maintained that the New Red Marl is more closely related to the Rhætic, and even to the Lias, than to the Bunter; and in support of this opinion he cited both stratigraphical and palæontological evidence. He described what he regarded as the sequence of events during the accumulation of the later Triassic deposits and the passage through the Rhætic to the Lias, and intimating that the same reasoning would apply to other British strata, especially some of those coloured red by oxide of iron, including the Permian, the Old Red Sandstone, and a part of the Cambrian. Mr. Etheridge thought the question of the nature of the Rhætic beds was to a great extent palæontological. The main point in connection with them was as to how the British beds were to be connected with the Lombardic and Middle European areas. It certainly seemed probable that in this part of the world the conditions of life were different, the deposits being much less in thickness, and the fauna much diminished; and where represented at all, the shells occurred in a dwarfed and stunted form. The exact horizon and nature of the Sutton beds had still to be determined. Mr. Godwin-Austen believed that every mass of red sandstone would ultimately be referred to either a brackish or freshwater origin. A comparison of the ancient and present area of the Caspian Sea would tend to remove any doubt that might remain on the mind of geologists as to the possibility of the existence of such vast internal seas as those which had to be called in to account for these formations. He regretted that former observers had not attached more importance to the duration and extent of those freshwater conditions which were found so commonly to have prevailed between the periods of deposit of the great marine formations. There was another fact to be borne in mind, that even in existing lakes the water at the one end was sometimes completely fresh, and at the other end salt, each, of course, with a different fauna. Prof. Rupert Jones said that, although there were good grounds for the lake-theory, something might be said for shallow seas. He remarked that sulphate of lime was deposited from sea-water before salt, that oxide of iron might originate from chloride of iron diffused in water whether of lakes or seas, and that the hæmatites of Permian age were probably deposited in the sea. He considered that Foraminifera required great caution when used as criteria, as the varietal forms giving the facies were of more importance than the genera and species. The *Estheriæ* were never marine, although often occurring in plenty in temporary freshwater pools on the sea-shore. In his monograph of *Estheria* he had said much to substantiate the notion that freshwater conditions often prevailed during the formation of the Keuper. Both in the Old Red Sandstone of the Baltic provinces and in the Lettenkohle and Keuper of Germany, when *Estheria* comes in, *Lingula* dies out. The *repeated* set of formations in the Permian and the Trias precludes their contemporaneity, as supposed by Messrs. Godwin-Austen and Marcou. Mr. Bauerman marked that the Hallstatt beds which had been cited as marine contained large deposits of rock-salt. M. Marcou thought that the difficulties in regarding these beds as of freshwater origin were greater than the author supposed. The absence of fossils in gypsum, though almost universal, was not total. He had himself seen three specimens of *Trigonia* in gypsum from Stuttgart. Mr. Tate mentioned the discovery by Mr. Burton of marine fossils in the Red Marl, in one instance in combination with vegetable remains. He commented on the sharp demarcation observable in Ireland between the Rhætic beds and the marl below, whereas it was almost impossible to separate them from the Lias above. He doubted, however, whether the true relations of the Rhætic beds were to be worked out in this country. As to the fossils of the Sutton Stone, they were all purely Liassic. Mr. Burton stated that the fossils from the Red Marl came from a spot about five miles from Retford, in the direction of Gainsborough, but he had not seen them *in situ*. There are, however, no Rhætic beds within some miles. Rev. Mr. Winwood, in the absence of Mr. C. Moore, from ill health, inquired whether the author regarded the White Lias as Rhætic or Liassic. Prof. Ramsay, in reply, was quite willing to accept marine fossils as coming from the Red Marl. The fact of *Estheria*, a brackish or freshwater form, occurring in certain bands, was in favour of his views, as he considered that at intervals the freshness of the water in such a lake as he had suggested must have varied. He could not accept the probability of oxide of iron having been deposited in a large sea area to such an extent as to colour the sands. All rocks that could be proved to be of marine origin, even when they contained iron, were not stained red unless by infiltration from above. He pointed out that the old area of the Caspian was far larger than the lake in which he had suggested that the New Red Marl had been deposited. If, as was more than probable, there had been during all geological time continental areas somewhat in the same positions as those of the present day, there must have been large areas of inland drainage in which some such deposits as those in question must of necessity have been formed.—2. "Note on a large Reptilian Skull from Brooke, Isle of Wight, probably Dinosaurian, and referable to the genus *Iguanodon*." By J. W. Hulke, F.R.S., F.G.S. The author stated that the skull described by him was obtained from a Wealden deposit at Brooke, in the Isle of Wight, from which many remains of Dinosauria have been obtained. He described its characters in detail, and remarked that its most striking peculiarities were:—the completeness of the bony brain-case; the obliteration of the sutures, especially those of the basicranial axis; the massiveness of the skull; and the great downward extension of the basisphenoid, with the attendant upward slant of the lower border of the basipresphenoidal rod. The first of these characters occurs elsewhere among reptiles only in *Dicynodon*; and the first and second characters combined were regarded by the author as approximating the skull to the ornithic type. The reference of this skull to *Iguanodon* was founded chiefly on the place from which it was obtained, which has furnished abundant remains of that genus, and on the obliteration of the sutures, which the author stated to be a character of the mandibles of *Iguanodon*. Prof. Huxley congratulated the society on the progress being made in our knowledge of this interesting group of reptiles and of their ornithic affinities. Mr. Seeley remarked on the similarity of the internal cavity of the skull to that of *Ichthyosaurus*. Some of the external characteristics differed much from what he was acquainted with in other Dinosaurian skulls, which more closely resembled those of ordinary lizards. He considered that the affinities of *Dinosaurs* were in the direction of *Teleosaurus*, from which the position of what were supposed to be the optic nerves in this skull materially differed. On the whole, he was not at once prepared to accept this skull as that of an Iguanodon. Mr. Hulke briefly replied, and observed that he had limited his speculations to those which legitimately arose from the facts before him. The following specimens were exhibited to the meeting :—Specimens from the Keuper Marls and Rhætic beds near Gainsborough; exhibited by Mr. F. M. Burton, F.G.S. Examples of the borings of two species of *Pholas;* exhibited by Mr. E. Charlesworth, F.G.S.

Zoological Society, February 7.—Mr. G. R. Waterhouse, Vice-President, in the chair.—The Secretary read a report on the additions to the Society's Menagerie during the month of January, amongst which were particularly mentioned a specimen of the kakapo, or night-parrot of New Zealand (*Strigops habroptilus*).—Mr. J. E. Harting exhibited and made remarks on a fine specimen of the red-breasted goose (*Anser ruficollis*) lately killed in England.—Mr. H. E. Dresser exhibited some specimens of rare European birds'-eggs, amongst which were those of *Micronisus brevipes* and *Reguloides superciliosus*.—Mr. E. Ward exhibited a skin of a white variety of the tiger (*Felis tigris*), obtained from an animal killed in the Mirzapore district.—Mr. W. B. Tegetmeier exhibited a specimen of an eel, believed to be new to the fauna of Great Britain. It had been obtained from fresh-water in the Scilly Islands, and was referred by Dr. Günther to a variety of *Anguilla vulgaris*, called *A. cuvieri* by Kaup.—A communication was read from Dr. Robert O. Cunningham, containing notes on some distinctive points in the osteology of *Rhea americana* and *Rhea darwinii*.—Mr. J. E. Harting read a paper on the Arctic collection of birds presented by Mr. John Barrow to the University Museum, Oxford, and drew attention to some interesting facts in connection with the geographical distribution of birds in northern latitudes.—A communication was read from Professor Carl J. Sundevall, containing an account of the birds obtained in the Galapagos Islands, during the voyage of the Royal Swedish frigate *Eugenia*.—Mr. R. B. Sharpe read a paper on the birds of Angola, founded on collections made in that country by Mr. J. J. Monteiro and Mr. Charles Hamilton, being his third communication on this subject.—Mr. J. Verreaux pointed out the characters of a new species of *Promerops* from Natal, which he proposed to call *Promerops gurneyi*.—Dr. J. E. Gray communicated a description of *Platasterias*, a new genus of *Astropectinidæ* from Mexico.—A communication was read from Mr. D. G. Elliot, containing the description of a new species of pheasant of the genus *Euplocamus* from Burmah, proposed to be called *Euplocamus andersonii*.—Dr. John Anderson pointed out the characters of three new species of squirrels (*Sciurus*) recently obtained by him during the Yunan Expedition. Dr. Anderson also gave an account of a new Cetacean which he had lately discovered in the Upper Irrawaddi, and which he proposed to call *Orcela fluminalis*. A third communication from Dr. Anderson contained a note on the occurence of the remarkable parasitic Crustacean *Saccalina* in the Bay of Bengal. The species, which had been found on the common swimming crab of that district (*Thalamita crenata*) did not appear to differ from that which is found on *Carcinus mænas* on the shores of Great Britain.

Royal Institution, February 6.—Monthly General Meeting. Sir Henry Holland, Bart., F.R.S., President, in the chair. Henry Edward Colvile, Esq.; John H. Dallmeyer, Esq.; Duncan Davidson, Esq.; Warren William De la Rue, Esq.; James N. Douglass, Esq.; Mrs. Gibbs; Abraham Goodall, Esq., F.R.C.S.; Alexander Macfarlan, Esq.; Robert Turtle Pigott, Esq., F.R.G.S.; Robert Sabine, Esq.; Charles Southwell, Esq.; Henry Stilwell, Esq.; Richard Valpy, Esq.; Mrs. Jacob Waley, were elected members of the Royal Institution. The presents received since the last meeting were laid on the table, and the thanks of the members returned for the same.

Entomological Society, February 6.—Mr. A. R. Wallace, President, in the chair.—Pastor Kawall, of Pussen, Kurland, was elected a corresponding member.—Mr. Bond exhibited *Pachinobia alpina*, *Gelacha borcella*, varieties of *Thera juniperata*, and *Larentia cæsiata*, and portions of web of *Hyponomenta padi* over a yard long, all from Perthshire; also photographs of eggs of bird parasites, taken from slides prepared by Mr. Norman. He likewise exhibited a curious instance of monstrosity in *Vanessa Atalanta*, the butterfly still retaining the larval head. —The Rev. H. S. Gorham exhibited *Oxytelus fulvipes* of Erichson, a new British beetle.—Mr. Müller exhibited specimens of oak-galls from Tangiers, collected by Mr. Blackmore.—Prof. Westwood exhibited a minute species of *Corixa* from India, destructive there to the eggs of the most valuable freshwater fish; also drawings of a species of *Coccidæ* injurious to the leaves of an exotic *Cypripedium*. The male shield consisted of a small disc, with six raised radiating lines produced into spines. —Mr. Butler read a descriptions of a new genus, and of seven new species of *Pierinæ*.

MANCHESTER

Literary and Philosophical Society, January 24. — Mr. E. W. Binney, president, in the chair.—Mr. Brothers exhibited a drawing from the fine photograph of the solar Corona, taken by him at Syracuse, during the late total eclipse of the sun.—Dr. Joule, F.R.S., read the following letter, dated January 21, 1871, which he had received from Mr. William H. Johnson, of Bowdon:—"Since the last meeting of the Philosophical Society I have made some further experiments on the 'Effect of cold on the strength of iron.' In these I have maintained a nearly fixed temperature, and thus avoided to a great extent the error occasioned by the rise in temperature, consequent on sudden torsion. January 11. A piece of a charcoal wire rod, ·237in. diameter, gave the following results :—

	1st.	2nd.	3rd.
At about 40° F. . . .	20 twists .	. 19 twists .	. 17 twists.
Adjacent 6″ at temperature of melting zinc .	10 twists .	. 9 twists .	. 7½ twists.

	4th.	5th.
Twisted very slowly, surrounded by salt and snow	19¼ twists.	. 16 twists.
Adjacent 6″ at about 40° F	15 twists .	.

The twisting under salt and snow was performed so slowly, each experiment lasting a quarter of an hour or more, that the temperature cannot have been affected by the torsion. The same care was taken at the temperature of 40° F. The great diminution of strength at the melting point of zinc is remarkable. I take the liberty of communicating these results to you, as unfortunately I shall be away at the next meeting, and thus shall not have an opportunity of seeing you." Mr. Brockbank remarked that these experiments did not affect the conclusions stated in his paper, read at the last meeting. He believed that the strength of iron under torsion was most affected by the heat developed by the twisting, and that the cooling mixture employed by Mr. Johnson would have the effect of making the wire stand a greater number of twists by counteracting the excessive heat produced by the torsion. Mr. Brockbank exhibited a drawing of the machine used by him in his experiments on the strength of cast iron at different temperatures.—"Experiments on the Oxidation of Iron," by Prof. E. Crace Calvert, Ph.D., F.R.S., &c. Some two years since Sir Charles Fox inquired of me if I could give him the exact composition of iron rust, viz., the oxidation found on the surface of metallic iron. I replied that it was admitted by all chemists to be the hydrate of the sesquioxide of iron, containing a trace of ammonia; to this he answered that he had read several books on the subject, in which the statements referring to it differed, and from recent observations he had made, he doubted the correctness of the acknowledged composition of iron rust. He further stated that if he took a bar of rusted wrought iron, and put it in violent vibrations, by applying at one end the fall of a hammer, scales would be separated which did not appear to him to be the substance I had described. This conversation induced me to commence a series of experiments which I shall now detail. I first carefully analysed some specimens of iron rust, which were procured, as far as possible, from any source of contamination. Thus one of these samples was supplied to me by Sir Charles Fox, as taken from the outside of Conway Bridge, the other secured by myself at Llangollen, North Wales. These specimens gave the following results when submitted to analysis:

	Conway Bridge.	Llangollen.
Sesquioxide of iron . . .	93·094 . .	92·900
Protoxide of Iron . . .	5·810 . .	6·177
Carbonate of iron . . .	0·900 . .	0·617
Silica	0·196 . .	0·121
Ammonia	Trace	Trace
Carbonate of lime . . .	—— . .	0·295

These results clearly show the correctness of Sir Charles Fox's foresight, that the composition of the rust of iron is far more complicated than is stated in our text-books. Therefore the question may be asked, Is the oxidation of iron due to the direct action of the oxygen of the atmosphere, or to the decomposition of its aqueous vapour; or does the very small quantity of carbonic acid which it contains determine or intensify the oxidation of metallic iron? To reply to it I have made a long series of experiments, extending over two years, and which I hope will throw some light on this very important question. Perfectly cleaned blades of steel and iron, having a gutta percha mass at one end, were introduced in tubes which were placed over a mercury trough, and by a current of pure oxygen conducted to the top of the experimental tube; the atmosphere was displaced, and it was then easy to introduce into these tubes traces of moisture, carbonic acid, and ammonia. After a period of four months, the blades of iron so exposed gave the following results:—

Dry Oxygen	No oxidation.
Damp "	In three experiments, only one blade slightly oxidised.
Dry Carbonic Acid	No oxidation.
Damp "	Slight appearance of a white precipitate of the iron, found to be carbonate of iron. Two only out of six experiments did not give these results.
Dry carbonic acid and oxygen . .	No oxidation.
Damp oxygen and carbonic acid	Oxidation most rapid, a few hours being sufficient. The blade assumed a dark green colour, which then turned brown ochre.
Dry oxygen and ammonia . .	No oxidation.
Damp " " . . .	No oxidation.

The above results prove that under the conditions described, pure and dry oxygen does not determine the oxidation of iron, that moist oxygen has only feeble action; dry or moist pure carbonic acid has no action, but that moist oxygen containing traces of carbonic acid acts most rapidly on iron, giving rise to protoxide of iron, then to carbonate of the same oxide, and lastly to a mixture of saline oxide and hydrate of the sesquioxide of iron. These facts tend to show that carbonic acid is the agent which determines the oxidation of iron, and justify me in assuming that it is the presence of carbonic acid in the atmosphere, and not its oxygen or its aqueous vapour, which determines the oxidation of iron in common air. Although this statement may be objected to at first sight, on the ground of the small amount of carbonic acid gas existing in the atmosphere, still we must bear in mind that a piece of iron, when exposed to atmospheric influences, comes in contact with large quantities of carbonic acid during twenty-four hours. These results appeared to me so interesting that I decided to institute several series of experiments. When perfectly clean blades of the best quality of commercial iron are placed in ordinary Manchester water, they rust with great facility, but if the water is previously well boiled and deprived of oxygen and carbonic acid, they will not rust for several weeks. Again, if a blade of the same metal is half immersed in a bottle containing equal volumes of pure distilled water and oxygen, that portion dipping in the water becomes rapidly covered with the hydrate of the peroxide of iron, whilst the upper part of the blade remains for weeks unoxidised; but if a blade be placed in a mixture of carbonic acid and oxygen, a very different chemical action ensues, as not only that portion of the blade dipping in the water is rapidly attacked, but the upper part of it immediately shows the result of chemical action, and also the subsequent chemical reactions are greatly modified by the presence of the carbonic acid. For in this case that portion of the blade is only covered with a film of carbon, together with a dark deposit composed of carbonate of the protoxide and hydrate of the sesquioxide. The fluid, instead of remaining clear, becomes turbid. These series of experiments substantiate the interesting fact observed—that carbonic acid *promotes* oxidation. A long series of experiments were also made to try and throw some light on the curious fact, first published by Berzelius, subsequently studied by other chemists, and well known to soap and alkali manufacturers, namely, that caustic alkalies prevent the oxidation of iron; my researches can be resumed as follows:—(1) that the carbonates and bicarbonates of the alkalies possess the same property as their hydrates; and (2) that if an iron blade is half immersed in a solution of the above-mentioned carbonates, they exert such a preservative influence on that portion of the bar which is exposed to an atmosphere of common air (oxygen and carbonic acid), that it does not oxidise even after a period of two years. Similar results were obtained with sea water, to which had been added carbonates of potash and soda.

Microscopical and Natural History Section, January 9.—Mr. J. Baxendell, President of the Section, in the chair. "On *Carex flava* L., and its allies, of the Manchester Flora," by Charles Bailey. The prevailing form in the district, and one very common to the south of Manchester, is the *Carex lepidocarpa* Tausch.; this is the *C. Œderi* Sm., and of Grindon's Manchester Flora, and the *C. flava* var. β of Buxton's Guide. The true *C. flava* (α *genuina* E.B.), as stated long ago by Mr. Buxton, is nowhere met with in the district. Specimens of *C. Œderi* Ehrh. from Mere Mere, the locality mentioned in Buxton's Botanical Guide, were recently exhibited at a meeting of the Society, and the sandhills at Southport are, so far as I know, the only locality in the neighbourhood for this species.

TAUNTON

Somersetshire Natural History Society, February 6.—The following notice was read by Mr. Cecil Smith.—The Great Bustard has now so long been considered extinct in England, that we may look upon it as interesting in an archæological as well as in a natural history point of view. This bird, one of a flock of eight that made their appearance on the last day of the old year at Braunton, near Barnstaple, in North Devon, is probably a young hen bird of the first, certainly not more than the second, year. On looking at this bird, perhaps, one of the first things that strikes one is the shape of the foot, the three toes in front and no hind toe; and this brings me at once to the subject of classification or order. Yarrell, whose system is best known and most generally adopted, has made the bustards a group of the Rasoreal order, where I cannot help thinking they are not a little out of place, there being no very nearly allied group in that order. I am much more inclined to agree with Baron Cuvier and some of the other older systematic authors who placed the bustards amongst the Grallatores or Stilted birds, where they seem naturally to fall into place next to their near relations, the Plovers; the absence of the hind toe, a conspicuous mark of the true Plover, would at once suggest this position. The form of the sternum or breast bone also points to a relationship with the plovers rather than with any of the Rasores. Another point which can scarcely be passed over in silence in a paper on the Great Bustard is the gulor pouch. It seems surprising that the use, and even the existence, of this pouch has so long been a matter of doubt and perplexity to naturalists. Much light has, however, lately been thrown on the subject by Prof. Newton, Mr. Bartlett, and Dr. Murie, and it seems finally to have been set at rest by Dr. Cullen, the result of whose examinations has been reported in the *Ibis* for 1865. He readily found the opening into the pouch under the tongue, and describes it as large enough to admit the little finger; the pouch itself, he says, extended as far down as the furcular bone, and was a separate and distinct, though delicate, bladder. He then describes the performances of the male bustard in the breeding season, at which time, he says, it makes a peculiar sound, resembling the word "ook," and he strongly favours the idea that the pouch is merely an organ of sound, and that it is acted upon by the muscular tissue covering it; in fact, that it is a sort of bird bag-pipe, and seems not to produce much more melodious sounds. Although the Great Bustard was formerly resident in England throughout the year, it is generally a migratory bird, its migratory propensities being much developed by stress of weather and scarcity of food; whether either of these causes or the war in France, has been the reason for the present unusual migration to England is perhaps difficult to say; myself, I should be inclined to think bad weather and the consequent loss of food the more probable cause. The gradual extinction of the Great Bustard in England has been the general theme of most of onr writers on ornithological subjects from the time of Bewick and Montagu to the present time of Mr. Stevenson, who in his still unfinished work on the "Birds of Norfolk," gives a most interesting account of the decline and fall of the Great Bustard in that county. In Devonshire, where this bird was killed, the Great Bustard, although never resident, seems from time to time to have paid occasional migratory visits. Montagu mentions the occurrence of one near Plymouth in the year 1798, two more in the next year, and one in 1864. Another Devonshire specimen occurred, after a long interval, on the 31st December, 1851, near Clovelly, and was recorded by Mr. Gatscombe, in the *Naturalist*. The 31st December seems to have been a favourite day with the Great Bustard in North Devon, for the flock, of which this present specimen was one, appeared on Braunton Burrows, near Barnstaple, on that day last year; the flock consisted of eight, and was first observed in a field near Croyde, where two were killed and one wounded. The remainder of the flock then alighted. Some boys, who were sliding close to Braunton, pelted them with stones, upon which the birds flew off, and were not heard of for some days; subsequently, I heard they were seen at Halsworthy, in the west of Devon, not very far from the border of Cornwall, but none were obtained there. In Devon they were considered to be wild turkeys, and the following paragraph appeared in the *North Devon Journal*:—"Wild fowl.—During Christmas week a flock of eight wild turkeys visited this parish, and alighted in a field at Croyde. They were seen by Mr. William Nuich, who followed and shot one which weighed 9lb., and was much admired. The others took their flight to the west, and have not since made their appearance." This migration of the Great Bustards was not confined to Devon alone, for in the February number of the *Zoologist*, specimens are reported from Middlesex, Northumberland, Wiltshire, and Somersetshire. The Somersetshire specimen is of course the most interesting to us: it was seen by Mr. Harting on the 27th of September, when journeying by rail from Bishops Lydiard to Wells in the low marsh country near Shapwick. His attention was first attracted by seeing a bird crouch at the approach of the train. He kept his eyes on the bird until the distance was considerably decreased, when the bird jumped up and ran swiftly away, exhibiting to his astonishment the long legs and white flanks of a bustard. Mr. Harting subsequently published an account of his interview with this bustard in the *Field*. He seems to have no doubt himself that the bird he saw was a bustard, and as he seems to have had sufficient opportunity to identify it, we must therefore take it that this Shapwick bustard was the pioneer of the December migrants, and that we have to thank Mr. Harting for this important addition to our Somersetshire avi-fauna. Although this migration has refreshed our memory of the Great Bustard for a time, I am afraid we must in England look upon it as a bird of the past, certainly as a resident, one or two migratory appearances like the present may no doubt from time to time stir up the ornithological world, and cause a temporary excitement; but that a bird of such considerable size and conspicuous plumage should for any time continue to exist in such a highly cultivated and thickly inhabited country as England seems impossible. Should it do so in any considerable numbers we should very soon have an outcry from some of our farmers, as it is addicted to feeding upon corn, both when green and ripe, and is moreover especially fond of turnip greens. No doubt in more ways than one the present system of high farming and the amount of machinery used is most fatal to the Great Bustard as a resident, and we must soon look upon him as having his memory perpetuated like the Druid,* only as the sign of a public house, and being classed by some future Mr. Weller with a "griffin, a unicorn, or a King's Arms, as is well known to be a collection of fabulous animals."

PHILADELPHIA

Academy of Natural Sciences, Nov. 8.—Mr. Thomas Meehan referred to a potato presented to the Academy some months ago by Mr. Henszey, a member, which had the appearance of one potato growing out of the centre of another. The opinion of all who saw it was that it was really a case of this kind. It had been handed to him by the curators, and on dissection, though no exact place of origin could be traced, there seemed nothing to indicate any other theory of origin than that one potato had really grown out of the centre of the other. But there were serious physiological reasons in the way of such a theory. A potato tuber is really but a thickened axis, in which the greater part of the interior structure would be incapable of developing a bud which would produce a tuber such as this one had done. The origin of a new tuber from an old one would be nearer the old one's surface. He had been looking for some further explanatory facts, and believed he had them here this evening, in the potato tubers he now handed to the members. They were about the size of hen's eggs, and were pierced in every direction by stolons of the common couch grass, *Triticum repens*. They had gone completely through, as if they were so much wire, and in one instance two tubers had become strung together by the same stolon, as if they were two beads on a string. One would suppose that the apex of the stolon, when it came in contact with the hard surface of the tuber, would turn aside and rather follow the softer line of the earth; but there was no appearance of any inclination to depart from their direct course. They had gone apparently straight through. He had no doubt the potato before referred to was a similar case, a potato stolon had penetrated another potato, and instead of going through as these grass spears had done, terminated in the centre, and formed the new potato there. It was worthy of thought whether so much attention had been given to this direct force in plants as the subject deserved. It was well known that a mushroom would lift a paving-stone many times its own weight, rather than turn over and grow sideways, which it would appear so much easier for it to do; and tree roots growing against walls would throw immensely strong ones over, though one would think the pressure against the softer soil would give room for their development, without the necessity of their expending so much force against the wall.

November 15.—Dr. Ruschenberger, President, in the chair. Prof. Leidy directed attention to some fossil bones which had been submitted to his examination by Prof. J. D. Whitney. According to the accompanying label, they were found under Table Mountain, near Shaw Flat, Tuolumne Co., California. The bones are friable, and have attached portions of a light ash coloured gravel. Several masses of the latter substance accompanying the bones, contain casts of some fruit. Prof. Leidy further directed attention to a fossil fragment of the lower part of a small pachyderm, which Prof. Hayden had obtained from Henry's Fork of Green River, Wyoming. The specimen contained the fourth, the sixth, and the seventh molars. The teeth resemble in form and constitution those of the *Lophiotherium cervulum*, a small pachyderm, described by Prof. Gervais, from an Eocene formation of France. The crowns of the fourth to the sixth molars have four lobes; that of the seventh molar has an additional lobe. The crescentic summit of the postero-external lobe joins, by its anterior horn, the antero-internal lobe. A proportionately well developed basal ridge embraces the crowns, except internally, where it is entirely absent. The series of the back four molars occupies a space of 16 lines. The last molar is $5\frac{1}{2}$ lines fore and aft. The base of the jaw is nearly straight the length of the fragment, which is an inch and a half. The depth of the jaw below the fifth molar is about an inch. The species may be named *Lophiotherium sylvaticum*.

November 29.—Dr. Ruschenberger, President, in the chair. On "Bud Varieties," by Thomas Meehan.—A few years ago Mr. Isaac Burk called my attention to a form of *Rubus villosus*, L., in which the terminal leaflet was very large, cordate, and on very long petioles. It is a very striking variety, the leaflets appearing at first glance like large linden leaves. On the idea that varieties originated from one common centre, it is not easy to account for the existence of the same forms so many miles apart, as we find in the above, except by the accidental carrying of seeds. But I have reason to believe that seeds of *Rubus* rarely germinate in a wild state. In experiments which I have made in raising the seeds artificially, none of the seedlings come exactly like the parent. There is a certain general resemblance, but some distinction, more or less, can be traced in each individual. But, in native places, one exact form will be found to occupy extensive tracts. Sometimes several forms will be together, but only a very few. If the seeds made plants readily, there would be innumerable forms, instead of the very few we see. I found, in my experiments, that it took a long time for a blackberry seed to germinate; sometimes a whole year. Such seedlings have a poor chance to vegetate in a state of nature. Other more rapidly-growing vegetation would crowd it out. The only distributing agency I can think of is that of birds. But I find no birds eat blackberry seeds; and, if they did, when we consider that of the millions of seeds which fall about the place of their origin, few, if any, grow; the chance of those growing which birds may carry, even if there be some to eat them, which I have failed to find, is extremely small. Hence, we find great difficulty in believing that identical forms of *Rubus*, widely separated, can have originated from a common centre. It is well-known that fruits, after being grown for some time in one locality, will change their characters to such an extent that a person acquainted with one will fail to recognise it elsewhere, and all this without the intervention of any seminal power. Thus, the nectarine is believed to be a bud evolution from the peach; the Penn apple is a similar creation from Baldwin, and the Reading from the common Isabella grape. Though apparently originating in this way from external or local causes, the characters peculiar in this

* The Druid and the Bustard are both the signs of public-houses on Salisbury Plain.

change are retained when, by grafts or cuttings, the plants are removed to other localities. I have here, however, and exhibit with this paper, evidence of bud variation, in which there is no possibility of hybridism,—a root of the common sweet potato, *Convolvulus batatas*, in which some of the tubers are of the red Bermuda, and the others of the white Brazilian variety. The sweet potato never flowers in this part of the country, so that seminal power could have had no influence whatever on the phenomenon. Even in the south, and I believe elsewhere, where this plant is cultivated for its roots, it rarely flowers, and I think there is little doubt but that the whole ten or twelve varieties under culture have originated without seed, and in the way we see them here. The points I wish to make in this paper are :—1st. That identical varieties sometimes appear in localities unfavourable to the idea of a common centre of origin. 2nd. Varieties have originated in which probably no hybridism or any seminal agency operated. 3rd. Varieties have certainly originated in the sweet potato by evolution, without seminal agency, and that the same variety in this way has appeared in widely-separated districts. 4th. As the discoveries of Darwin have shown, in many cases, varieties to be the parents of species, species may originate in widely-separated localities by bud variation.—"A Sketch of the Classification of the American Anserinæ," by B. H. Bannister. The following remarks are based upon an examination of the specimens of American geese in the collection of the Smithsonian Institution. The subfamily Anserinæ by many recent authors is made to include the genera *Dendrocygna* and *Chenalopex*, and doubtlessly correctly. In the present paper, however, we shall not consider these genera, leaving them provisionally out of the sub-family ; if included, they would form at least one well-marked section, following those we are about to describe. The distinguishing characters of the Anserinæ, as thus limited to the true geese, are, the lengthened tarsus, covered with hexagonal or subquadrate scales ; the neck more elongated than in the ducks and less so than in the swans ; the short, high bill gradually narrowing toward the tip, which is altogether composed of the large recurved nail ; together with the more or less terrestrial habit of life, and the usually similar plumage of the two sexes. The geese of the North American continent have been long known, and being for the most part closely allied to, and in many cases identical with, well known European forms, they fall readily into the systematic subdivisions based upon the latter. Another basis of division of the American Anserinæ is found in the presence, in two species—one North American and the other a Southern form—of deep rough superorbital depressions and reversed relative proportions of the tarsus and middle toe, together with an exclusively sea-coast habitat, and a carnivorous diet, corresponding in some of these respects to the Oidemiæ and Somateriæ amongst the ducks. These latter characters we have taken as the basis of the two sections into which we divide the subfamily, as at present considered, since they correspond with equivalent characters in one of the subdivisions of the Fuligulinæ. The presence of the deep superorbital depressions is a very general character amongst the carnivorous Natatores, though not universal.

THE MEDITERRANEAN ECLIPSE, 1870

II.

IN my former article under the above title, written from Venice, I gave as shortly as I could the conclusions at which I had arrived as to the results of the various Eclipse expeditions as gathered from the very imperfect information then at my disposal. Since I returned home, I have naturally become possessed of more facts, though even yet the time has not arrived for discussing all the observations as they must be discussed before an absolutely final verdict can be given.

Still, there is so much general interest taken in the recent work, that I venture to return to it at the present time, more especially as I can now print a letter from a distinguished American astronomer, giving his view of the work done, and also as I am anxious to refer to Prof. Young's article which has recently appeared in NATURE.

Prof. Peters, whose long and laborious researches on the sun are well known to all of us, thus writes in reference to my former article:—

"Its perusal has been to me a source not only of pleasure but of much instruction. You have placed on record, with great lucidity, the question as it stood before the Eclipse, and the points to be examined by the various ways of observation for bringing the question nearer to its solution. Although the unfavourable state of the weather over the entire zone of totality, as it seems, from Spain to Sicily, has greatly obstructed the execution of the plans and the extensive preparations made with the liberal aid of our respective governments; and although hitherto, of course, only imperfect, mostly verbal, information has reached us of what the parties really did succeed in obtaining—still the result that is to be drawn from the sum total, as you are showing, seems of importance. The spectroscopic, polariscopic, and telescopic observations altogether agree in demonstrating an interior portion of the corona to belong to the sun. The existence of such a *solar* stratum is sustained also by my researches on the motion of spots when near the limb, pointing to a refraction on, or rather above, the sun's surface. I concur further in your opinion that the outer, more irregular radiating portion of the corona very likely owes its origin to our atmosphere. It is highly to be regretted that our Etna parties, in elevations respectively of 3,100, 5,500 and 8,000 feet, suffered disappointment from a heavy cloud at the critical moment of totality. Their observations would have been decisive as to the local and atmospheric cause of the radiating coronal phenomenon."

One more extract before I proceed. With reference to the suggestion (based on my observations of injections into the chromosphere) contained in my article, that probably the green line seen in the spectrum of the Corona might indicate a new element lighter than hydrogen, Prof. Young, claiming priority in the suggestion, writes:—

"In *Silliman's Journal*, November 1869, I wrote, 'should it turn out that this line in the spectrum of the aurora does actually coincide with 1474, it will be of interest to inquire whether we are to admit the presence of *iron vapour* in and above our atmosphere, or whether in the spectrum of iron this line owes its origin to some foreign substance, probably some occluded gas as yet unknown, and perhaps standing in relation to the magnetic powers of that metal.'

"This is the only reference I am able to make here. In my paper published in the Proceedings of the American Association for 1869, the same thing is, I think, more forcibly expressed. I think you will find it also in my Eclipse Report in the 'Journal of the Franklin Institute' (and in my letter to NATURE last spring).

"The idea that 1474 might represent some new element occurred to me at once when I found it in the Corona, but of late I own I have more inclined to the opinion that it might possibly be a true iron line, and caused by meteoric iron dust of almost infinitesimal fineness; yet I have always felt the difficulty of supposing the complicated iron spectrum reducible to this one line."

I feel it due to Prof. Young to give this extract, though I confess I do not see that the suggestions are similar, nor do I see anything similar in the letter referred to, though I have lighted upon this passage which I had forgotten, which shows the great advance that has been made. Prof. Young last year wrote* "It is not impossible that the so-called corona may be complex. Some portion of its radiance may, *perhaps*, originate in our own atmosphere, although I do not yet find myself able to accord with the conclusions of Dr. Gould and Mr. Lockyer in this respect, and am strongly disposed to believe that the whole phenomenon is purely solar." His present views were given to the readers of NATURE three weeks ago, as in the main concurring with my own.

With reference to Prof. Young's article, I am anxious to say one word on the "sudden reversal into brightness and colour of the countless dark lines of the spectrum at the commencement of totality," witnessed by himself and Mr. Pye. I have seen this *once*, and only once, during all my observations, and Professor Young (who enjoys better atmospheric conditions than I do) has never seen it when working with the new method. Now, I hold that the new method is competent to pick up such an envelope as the one referred to by Mr. Longley, if it can pick up an uprush similarly composed; and although of course the vapours competent to give such lines are not far off, as the ordinary observations prove, I do not think they are ordinarily high enough above the level of the photosphere to be seen in this manner. That the number of lines is largely increased when the atmospheric glare is withdrawn, was proved during the American Eclipse.

But to return to the Corona, the main point of attack during the last Eclipse. Since my last article was written I have had an opportunity of inspecting copies of the beautiful photographs taken by Mr. Brothers at Syracuse, and also one of the photographs taken by the Americans in Spain. These, compared with the sketches taken at the respective stations, are very curious. In the Spanish photograph there is a very distinct "rift," or dark space in the coronal region, extending, I believe, almost to the sun, and fainter indications of two other such rifts in another region, not extending so low down in the Corona. So far as the facts have yet been before me, only one of these rifts was sketched. Now, at Syracuse Mr. Brothers also photographed rifts—three rifts; but the sketches did not record a single one. In Prof. Watson's drawing, a copy of which I have now in my possession, there is no indication whatever of them. But there is a much more important fact behind. Of course, if these rifts had been in the same positions in the two photographs, taken at stations so wide apart as Spain and Sicily, the presumptive evidence in favour of the solar nature of the Corona for a distance outside the sun equal to

* NATURE, vol. i. p. 533.

its diameter would have been overwhelming, and feeling that here was a crucial test to apply to a question which has so long been debated, but never with such interest among the workers as recently, it was with some excitement that I found myself before these two photographs some little time ago with two American astronomers of eminence, for the purpose of endeavouring to settle the question. Suffice it to say that we came to the conclusion that the rifts were not identical, that the two cameras had *not* photographed the same phenomenon, although at first there appeared to be sufficient similarity to make the matter appear doubtful, and, unfortunately, the photographs vary so much in size, and the margin of the American one is so limited, that it will be scarcely possible to make a final comparison until they are brought to a common scale, and superposed the one on the other. I do not think it is surprising that rifts should appear in both photographs, supposing a non-solar cause were at work, for the Corona between the rifts on Mr. Brothers' photograph looks like a very wide ray.

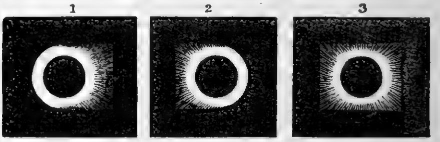
Assuming then for the present that the photographic evidence goes the way of all the other evidence—that in short, the solar corona, including all its fantastic boundaries, has been probably reduced from one, two, or three solar diameters, to six, eight, or ten minutes,—I care not which,*—let us examine some of the details of the various observations.

In Professor Watson's drawing, the intimate connection between the higher and lower levels of the chromosphere (including the portions not at present observed by the new method), comes out in a very striking way. Mr. Seabroke at my request, made careful maps of the positions of the prominences before the totality commenced, and Professor Watson made his drawing of the Corona, independently of the positions of the prominences. On the homeward journey the map was compared with the sketch, and to use Professor Roscoe's words, "On comparing the two drawings thus independently made, a most interesting series of coincidences presented themselves. Wherever on the solar disc a large group of prominences was seen in Mr. Seabroke's map, there a corresponding bulging out of the Corona was chronicled on Professor Watson's drawing, and at the positions where no prominences presented themselves, there the bright portions of the corona extended to the smallest distances from the sun's limb." We may remark that these coincidences show the excessive fidelity of the drawing, and make it one of the most valuable of the products of the Expedition.

On former occasions the Corona has been stated to assume a roughly four-cornered form. This was also observed in Spain last December, and seems at last explained by three drawings made by one of the American party there.

At the commencement and end of totality, when the moon unequally covered the sun, the photographs have recorded an excess of light on the Corona on the side where the limbs occur nearest in contact. I am told that this effect in one of Lord Lindsay's photographs is very striking; it is certainly so in one of Mr. Brothers'. In the drawings we have a slightly different effect. At the commencement of totality, when the western or right hand limbs were in contact, we get Fig. 1, at the end of totality the appearance recorded was Fig. 2; the picture at the middle

1 2 3



of totality compounding both these appearances, and being roughly represented by Fig. 3, in which the rectangular appearance comes out in its full strength.

A word now about the polariscopic observations. I may remark on this that it is much more easy for us to explain slight polarisation which might be atmospheric, than it is to explain, if we content ourselves with laboratory experiments, strong *radial* polarisation which must take place at the sun. If we assume that gas or vapour of considerable tenuity does not reflect light (although I think this is to assume very much for the gas or vapour *at the sun*, at all events), what is it that reflects light to us at the sun, and reflects it apparently only *above* the level of the intensely incandescent hydrogen? Certainly not solar spray. If we deny reflection to gases altogether, may it not be the continuous portion of the spectrum of the gas itself to which the light is due. But this question of polarisation is certainly one in which very much remains to be done, and it is consoling to know that the results obtained now will much facilitate the planning of the next polariscopic campaign, which, we may add, should not be deferred beyond the end of this year.

J. NORMAN LOCKYER

* I beg here to give the actual words employed by Dr Frankland and myself in the communication to the Royal Society on the subject. Speaking of the chromosphere, it was remarked "the tenuity of this incandescent atmosphere is such that it is extremely improbable that *any extensive atmosphere*, such as the corona has been imagined to indicate lies outside it"—Proc. R.S., Feb. 11, 1869. I never imagined that all the Corona was non-solar. Again, Proc. R.S., No 116, 1870 discussing the American Eclipse, I state that the chromosphere includes the "radiance" observed in the American Eclipse, of which radiance Dr. Gould wrote as follows:—

"An examination of the beautiful photographs made at Burlington and Ottumwa . . . and a comparison of them with my sketches of the corona, have led me to the conviction that the radiance around the moon in the pictures made during totality is not the corona at all, but is actually the image of what Lockyer has called the chromosphere. This interesting fact is indicated by many different considerations. The directions of maximum radiance do not coincide with those of the great beams of the corona; they remain constant, while the latter were variable. There is a diameter approximately corresponding to the solar axis, near the extremities of which the radiance upon the photographs is a minimum, whereas the coronal beams in these directions were especially marked during a great part of the total obscuration. The coronal beams stood in no apparent relation to the protuberances, whereas the aureole seen upon the photographs is most marked in their immediate vicinity. . . . . Whatever of this aureole is shown upon the photographs was occulted or displayed by the lunar motion, precisely as the protuberances were. The variations in the form of the corona, on the other hand, did not seem to be dependent in any degree upon the moon's motion. The singular and elegant structural indication in the special aggregations of light on the eastern side may be of high value in guiding to a further knowledge of the chromosphere. They are manifest in all the photographs by your parties which I have seen, but are especially marked in those of shortest exposure, such as the first one at Ottumwa. In some of the later views they may be detected on the other side of the sun, though less distinct; but the very irregular and jagged outline of the chromosphere, as described by Janssen and Lockyer, is exhibited in perfection."

PHYSICAL LABORATORIES

IN an excellent article in a late number of NATURE, Prof. Pickering has drawn attention to the importance of the practical teaching of Physics, and has shown how this is being done on an extensive scale in America. It may be interesting to trace the similarity between the methods employed by different teachers, and to show what opportunities are and have for some time past been open to students in London for the practical study of every branch of Physics.

Professors of Physics at different Universities have usually selected their best students to assist them in their private laboratories, to the mutual advantage of professor and student, but I believe that Prof. Clifton was the first to propose, more than three years ago, that a course of training in a physical laboratory should form a part of the regular work of every student of Physics.

This system was adopted and at once put in action at King's College, on a very considerable scale for a college with no endowment whatever, and has been working for now nearly three years. Two large rooms adjoining the Museum of Physical Apparatus were fitted up for a Physical Laboratory, and a third room was built for a store and battery room. Fixed tables in both large rooms are supplied with water and gas, and with pipes passing to gasholders containing oxygen and hydrogen, also with thick copper wires insulated from one another passing to the battery room, so that in electrical work the fumes from batteries are entirely got rid of.

The principal instruments have their fixed places on the tables, and a description of the measurement to be made is given to each student, and while in progress his work is examined by the professor or demonstrator. The course of study includes the subjects of pneumatics, heat, light, electricity, and magnetism, and with the regular class, a definite order in each subject is kept to as nearly as possible. When, as has sometimes been the case, there are twelve or more students beginning their laboratory course at the same time, it is necessary to deviate from the regular course, and to set some to begin with heat, some with light, and others with electricity. For some experiments, such as the determination of the relation between the pressure and volume of a gas, or the measurement of the expansion of a gas for given changes of temperature, requiring the use of the manometer and cathetometer, it is found better to have two students working together, each student making in his turn and so checking every part of the measurement or determination.

The accuracy of the results obtained has been very great, and is an evidence of the interest taken in the work by the student, and of the value of such a course of study as a mental training, to say nothing of the actual knowledge gained. Every student is required to produce fair results, and to give an account of the methods which he has employed, before he is allowed to proceed to another part of the subject. Besides the students pursuing the regular course there are several who wish to devote their attention to some one branch, such as Electricity. In this subject, after making determinations of Resistance, Strength of current, and Electromotive force with simple galvanometers, they pass to more delicate measurements with Thomson's Galvanometers and Electrometers, such as the experimental determination of equi-potential lines on a conducting surface uniting two poles of a battery, and perform all the tests and measurements required in connection with Telegraph lines and cables.

The more advanced students carry on investigations in the Laboratory, such as the measurement of the effect of heat in altering the magnetic polarity of dia-magnetic bodies, or in altering the rotation of the plane of polarisation of a beam of polarised light as it passes through sugar solutions.

Students are encouraged to combine their work in the Physical Laboratory with their work in the Mechanical Workshop, and are enabled to design and construct apparatus, and their inventive powers are exercised often with great success. From experiments with Attwood's Machine one student has designed and made for himself a new form of governor for an engine, another has designed an Inductometer for measuring the time required to produce the maximum induced current in a wire by the action of another current.

The success of the Laboratory system of teaching may be judged from the quality of the work done by the students, who are mostly from sixteen to eighteen years of age, and are always eager for the work, as well as from the fact that in the last term there were twenty-three students in the Laboratory, and the numbers are steadily increasing.

It will be seen that to the student of Electricity or any branch of Physics, every opportunity is offered of pursuing the object which lies before him, and that the advance which may be made by him is dependent only on his own exertions.

W. G. ADAMS

MORELL'S GEOMETRY

The Essentials of Geometry, Plane and Solid, as taught in French and German Schools, with shorter Demonstrations than in Euclid; adapted for Students preparing for Examination, Cadets in Military and Naval Schools, Technical Classes, &c. By J. R. Morell, formerly one of Her Majesty's Inspectors of Schools. (London: Griffith and Farran, 1871.)

A WORK with this attractive and somewhat ambitious title cannot fail to attract attention, appearing, as it does, at a moment when very commendable efforts are being made to improve the teaching of Geometry in our schools, and to prepare the public mind for an important reform which will necessarily involve the adoption of text-books more suited to modern habits of thought and inquiry than the Elements of Euclid. It will, no doubt, therefore be expectantly read by many, and the fact that the author is already widely known as a writer on philosophy and grammar, and was formerly one of Her Majesty's Inspectors of Schools, will tend to raise expectations, and will lend it an authority to which, as we shall presently see, it is by no means entitled. Our duty to students preparing for examination compels us, in fact, to warn them that this book can render them no essential service whatever, but, on the contrary, may do them incalculable mischief; and our sympathy with the praiseworthy efforts above alluded to—our desire to prevent undeserved discredit from being attached to those efforts—obliges us to dissociate this one from them, and to criticise it with all due severity.

The plan and general arrangement of the book are open to the severest criticism; we deem it unnecessary, however, to dwell thereon, for the work is so destitute of the most essential of all "Essentials of Geometry"—accuracy and clearness—that no possible rearrangement of its materials could redeem it. We shall consequently draw attention solely to the deplorable looseness of expression, indicative of hopeless inaccuracy of thought with which almost every page is disfigured.

We shall commence with quoting a few definitions, and simply italicising their most salient incongruities. Further comment will rarely be needed.

"Extension is the *space* occupied by a body" (p. 1).

"A straight line is that which has all its *points* in the same *direction*" (p. 1). Direction is, of course, not defined, nor is it stated whence the points of the line are supposed to be viewed.

"A plane angle is the *greater* or *less* inclination of two straight lines *to a common point*" (p. 5). In a note hereto the author complacently observes that "our definition accords with Euclid, Bk. i., n. 8."

"The angle A O B increases continually *in proportion* as the straight line O B takes the direction O C, O D, &c." (p. 6).

"The name adjacent angles is given to those angles that have one side common" (p. 6). The author appears to have felt that there was some insufficiency here, but instead of expunging the passage as wholly useless, he tries again in small print, and almost, though not quite, succeeds. That some haziness still clings around his conception of adjacent angles is obvious; for when we come, in the Geometry of Space, to angles between two planes, dihedral angles, we are told (p. 90) that "adjacent dihedral angles are those which have a common plane, *and whose other two sides are in one plane*." The condition here italicised is wholly unessential, and the really essential one is again omitted; viz., that the two angles should be on opposite sides of their common plane. This misconception of the nature of adjacent dihedral angles leads the author, naturally, to the following absolutely false definition:—"If two adjacent dihedral angles are equal, each one is named a dihedral right angle." We may here observe that there is deplorable confusion in this part of the work between polyhedra and polyhedral angles. Trihedral angles are generally, though not always, termed *trihedra*, dihedral angles occasionally crop up as *dihedra*, and uncouth entities such as *polyhedrals*, *dihedral sides* of a polyhedral angle (p. 94), and *polyhedral triangles* (p. 95), not unfrequently stop the way.

Leaving definitions, however, let us glance at Mr. Morell's enunciations of theorems, and the "improved shorter demonstrations" of them with which he supplies us.

On p. 3 we find the following short paragraph, into which a theorem and its demonstration are supposed to be condensed:—"Any diameter whatever divides a circumference into two equal parts; *therefore* if on superposing its two halves they did not agree, the radii of the same circumference would be unequal, which is absurd." The word *therefore* would imply that the assertion which precedes it is not itself the theorem to be demonstrated, but one which is to be employed in demonstrating something else. But what is this something else? Long reflection failed to furnish any answer to the question; it seemed but to give to the last three words a more extended significance than the author could have contemplated.

The entire paragraph remained a mystery to us, in fact, until we reached p. 25, when Mr. Morell's happy arrangement enabled him to return to the subject in these slightly modified words:—"Every diameter divides the circumference into two equal parts; *for* if on placing one *half* on the other they did not coincide, the radii of one and the same circumference would be different in length, which is absurd." Here the word *for* being substituted for *therefore*, we can no longer doubt that what precedes it *is* the theorem to be proved; the moment one *part*, however, is termed a *half* the whole question is begged; and even if this gross blunder had been avoided, the demonstration would still have been worthless, so long as the *mode* of placing one part on the other was left wholly unexplained.

The enunciation and demonstration of the two fundamental theorems of parallels are thus given on p. 21:—

"If two straight lines are parallel, and are cut by a secant, the alternate angles are equal, and also the corresponding angles. Conversely, if two straight lines cut by another form equal alternate or corresponding angles, the said lines will be parallel."

"For two alternate internal, or alternate external, or corresponding angles are both either acute or obtuse, and *consequently* equal in the case of parallels. But, if of two internal or external angles on the same side, one is acute, and the other obtuse, these angles are, *therefore*, supplementary."

Let the reader picture to himself for a moment the perplexity of the misguided student, "preparing for his examination," as he vainly strives to extract a meaning from this sheer nonsense. Distrustful of his own powers, the poor fellow will probably attribute his failure to his own incapacity, and in despair commit the precious passage to memory for the purpose of reproduction when his hour of trial shall come. The consequences of such rashness need not be stated. And yet Mr. Morell cites a respectable French geometer as an authority for this "shorter demonstration!" It was with no small curiosity that we turned to the pages of Amiot's *Éléments de Géometrie* to see how an author, who usually writes with admirable clearness, though not always with desirable rigour, could have been made responsible for such absurdity. The process was simpler than we expected; editorial scissors had simply clipped away everything worthy of the name of demonstration, and the editorial pen had garbled the feeble residue into the chaotic sentences above reproduced. We know of no epithet too severe to apply to editorial transgression of the kind here exposed.

To proceed with the painful task we have imposed upon ourselves, we have next to draw attention to two blunders, not in geometry, but in simple logic. On p. 20 we read as follows:—

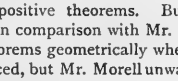
"It is often assumed as a self-evident proposition that through a given point only one parallel can be drawn to a straight line," and, in a foot-note hereto, we are told that "this is the *opposite* of Euclid's 12th axiom, similarly assumed to base upon it his theory of parallels." Had Mr. Morell read Amiot, even, with anything like attention he would have seen that this is not the case. In forming the opposite of a theorem, the new hypothesis and predicate must be made to contradict, respectively, the original hypothesis and predicate. The opposite of Euclid's 12th axiom, therefore, as Mr. Morell may now convince himself by trial, is very different from the one above quoted.

On p. 44 again, we have this marvellously short enunciation and demonstration of Euclid's Prop. 8, Book I.; "Let A B C, D E F be two triangles, having A B = DE

A C = D F, and B C = E F. Then angle A = D; *for if they were unequal, sides B C and E F would be unequal. Therefore* A = D." In violation of the most obvious of all logical rules, Mr. Morell here professes to prove a theorem by the simple assertion of it in its contra-positive form! To assert that B C and E F would be unequal if A and D were unequal is *logically equivalent* to saying that A and D would be equal if B C and E F were equal, which is precisely the proposition to be proved. The truth of either of these statements involves that of the other by the necessary laws of thought, and neither can be said to require geometrical demonstration more than the other. It is true that Euclid himself (*vide* Props. 7 and 9, Book iii.) overlooked this necessary relation between contra-positive theorems. But Euclid's error was very trivial in comparison with Mr. Morell's. Euclid proved *both* theorems geometrically when a proof of one would have sufficed, but Mr. Morell unwarrantably *asserts* the truth of one, and imagines he has thereby proved the other.

Notwithstanding the fact that Mr. Morell devotes a considerable part of his book to the approximate calculation of the ratio of the circumference of a circle to its diameter, we fear that he must henceforth be classed amongst the "circle squarers of the period." For, as is well known, the solution of this vexed problem is at once reducible to that of the rectification of the circumference; and on page 62 we find it stated that "the graphic construction which *gives us the length of the circumference in a straight line* is the following." For obvious reasons we forbear to reproduce it.

The "technical classes" to whom Mr. Morell professes to have "adapted" his text-book, will, we fear, derive as little profit from its pages as the "students preparing for examination." How can it profit them, for instance, to be told that "many public buildings have as façade a front elevation like A F B?" Yet it is



with this *isolated* technical observation that Mr. Morell terminates the forty-first page of his book. Again, what earthly, not to say technical use can they make of the three very bad pictures of a surveying rod, a Gunter's chain, and a measuring tape, with which they are favoured on page 36? On page 37, Mr. Morell starts with his technical class to determine a straight line through "a winding narrow street;" but he fails utterly to bring them round the very first corner. On page 38 he proposes to show them how "to draw *a* perpendicular bisector of a given straight line in nature," but we will not disfigure this page of NATURE with a reproduction of his unintelligible method. Although readers might be amused by it, we are not in a humour to extract amusement from a work which was certainly not written for the purpose of providing it, but with the serious intention of teaching Geometry in an improved manner.

We have by no means exhausted the incongruities of the book; but we have, we think, sufficiently shown that the teaching of Geometry cannot but be vitiated by its use; that, in fact, this text-book of Her Majesty's ex-Inspector of Schools will itself bear no inspection whatever.

RODWELL'S DICTIONARY OF SCIENCE

A Dictionary of Science: comprising Astronomy, Chemistry, Dynamics, Electricity, Heat, Hydrodynamics, Hydrostatics, Light, Magnetism, Mechanics, Meteorology, Pneumatics, Sound, and Statics. Edited by G. F. Rodwell, F.R.A.S., F.C.S. (London: E. Moxon and Co., 1871.)

THERE are Dictionaries and Dictionaries. We have had occasion to expose the shortcomings of some books that are called by this name; it is a far pleasanter task to direct attention to the merits of a work like the one before us, which really deserves its title. Mr. Rodwell's "Dictionary of Science" is a repertory of facts connected with physical science, which will be invaluable to the student. From Chemistry to Chladni's Figures; from Thermo-dynamics to Turacine, scarcely a term will be met with in scientific works, of which the learner will not here find an explanation. The articles have the great advantage of being short, and presenting the salient points of each subject at a glance before the reader's eye; and that their scientific accuracy may be relied on, is guaranteed by such names (amongst others) as those of Mr. Crookes, Prof. Guthrie, and Mr. Wormell in the list of contributors. To illustrate the style of the book, we cannot do better than select two of the shorter articles. The first is on a subject which has recently been discussed in these columns:—

"*Mass.*—Mass is a term for the quantity of matter in a body. In order to measure mass, we assume that the attraction of the earth on all particles of matter is the same, and is not dependent on the nature of the matter attracted. This assumption seems to be justified by the fact that bodies of all kinds fall with equal velocity in the exhausted receiver of an air-pump. Hence we measure the mass of a body by its weight, and can only define the mass as a quantity proportional to the weight. If, then, at the same spot of the earth's surface, one body is twice as heavy as another, the mass of the first is twice that of the second. Suppose, however, that the body be weighed by a spring-balance at a certain place, and weighed again by the same instrument at another place nearer the equator, it will be found that the body is lighter at the latter place. It is found also that the acceleration due to the attraction of the earth is also less at the second place than at the first, in the same proportion. This illustrates the fact that when the mass remains the same, the weight varies as the acceleration of gravity. Hence the weight varies as the product of the mass and the acceleration of gravity, and, consequently, when suitable units are chosen, the mass of a body is equal to its weight divided by the acceleration due to gravity."

Our next extract is chemical:—

"*Alcohol.*—By this name, when standing by itself, is usually understood the second term of the series of ordinary alcohols, or vinic alcohol. It is a transparent, colourless, mobile liquid, of a specific gravity 0·7939 at 60° F.; it boils at 74·4°C. (173·1 F.); its vapour density is 1·613; its formula is C_2H_6O; it is the spirituous principle of wine, beer, and spirits, and is produced by the fermentation of sugar, which is split up into alcohol and carbonic acid. In the diluted state alcohol is sometimes called spirits of wine. It is difficult to render anhydrous; distillation alone will not produce an alcohol containing less than 9 per cent. of water, and this remaining quantity must be removed by adding something which unites with the water chemically, as quick-lime. By oxidation it is converted into aldehyde, and then into acetic acid, but other products of oxidation are obtained in less quantity; these are formic acid, acetal, acetic ether, saccharic acid, gloxal, glyoxilic acid, and glycolic acid, the final products being water and carbonic acid. When the elements of water are removed from absolute alcohol, ether is formed."

Now for a few words of criticism, or rather of suggestion. The book is not quite free from mistakes, probably in most cases printers' errors, which ought by all means to be avoided in a Dictionary, and will doubtless be corrected when a second edition is called for, which we hope may be very soon. But what we find most fault with is the cross-references, which are needlessly complicated, and often misleading. Being anxious to see what was said about the latest discoveries in Spectrum Analysis, we turned to the article under that heading, which we found to be very clear as far as it went. At the end we were referred "for further information" to five other articles; of these, "Spectra of the Elements" and "Metallic Spectra" are not to be found; "Spectra, Metallic," does occur, but simply refers us again to "Coloured Flames," under which we found only two lines relating to spectroscopy. Neither of the articles referred to gave us any further information of importance on the subject.

One other criticism on another sentence in the preface. We observe with pleasure that this is to be the first of a series of similar dictionaries, which shall embrace the other departments of Science. One, it is stated, will have for its subject the "classificatory sciences" of Botany and Zoology. Now we must protest against the use of this term as applied to the two sciences named. Zoology and Botany have their physiological as well as their systematic side, and far the more important of the two. We trust that the forthcoming dictionaries will be framed on no such narrow basis as that implied in the denunciations by Mr. Emerson and Mr. Ruskin of the pursuit of botany as "a mere science of names." When these volumes are published, some confusion may possibly arise from the title "Dictionary of Science" having been given to this work, when it should have been more correctly "Dictionary of Physical Science."

The book is however an indispensable addition to the library of every student, and we cordially recommend it to the notice of our readers.

A. W. B.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Ocean Currents

I do not altogether agree with Mr. Johnston in concluding that his suggestion as to the influence of barometric differences on Ocean Currents was stated with insufficient clearness. His words were:—"The waters which lie under the high pressure area have a tendency to escape from under the excessive weight, towards the space over which the pressure is less;"—and about the meaning of this sentence there can be no dispute. It seems to me rather that Mr. Johnston, in his letter in NATURE for Feb. 2, is changing his ground; and whilst he formerly distinctly suggested the probability of the currents being due to mean differences of pressure stationary over certain oceanic areas, he now wishes to attribute them to the *motion* of centres of low pressure. This is quite a different thing, and is so far admissible, that what Piddington aptly called "storm-currents," attendant on tropical cyclones, are undoubtedly caused in such a way. But these storm-currents are very exceptional; within the tropics, where their excessive development renders them most noticeable, they occur only in the hurricane months, and even then only at intervals; they have clearly no connection with the continuous current which flows west all through the year, and besides the great depressions of the barometer which give rise to these, there are no others. The barometer in tropical latitudes is remarkably constant, and shows no centres of low pressure passing continually towards the west, in the direction of the Trade-winds or the Equatorial Currents. The Equatorial Currents are thus clearly not due in the slightest degree to differences of barometric pressure, either to those that are stationary, as Mr. Johnston now seems to admit, or to moving ones which exist only at rare intervals.

It is however certain that centres of low pressure, round which the air circles, do very frequently pass along in temperate latitudes, driven (it seems to me) by the prevalent west wind. In our own latitudes, and more especially in the winter months, these succeed each other at intervals of a few days, and though their action is intermittent, and for the most part peculiar to winter, I see no reason to doubt that they carry with them a species of storm-current, which does occasionally modify and even intensify the prevailing easterly drift. But it is in the highest degree improbable that the *formation* of these centres of low pressure can give rise to any appreciable currents. Even towards the centre of a cyclone, the barometric gradient does not exceed one inch in fifty miles; which, so far as its effect on the ocean is concerned, is equivalent to a difference of water-level of one-fourth of an inch in a mile; and even this can only exist if we suppose the barometric depression to be formed almost instantaneously. There is no evidence that it is so formed; and the longer it takes to arrive at its maximum, the more gradually does the water rise into the central space, and the more infinitesimal is the velocity with which it does so.

Mr. Johnston rightly corrects the slip which appeared in my former letter, of twenty miles *an hour*, instead of *a day*, and thinks that even twenty miles a day is too large an estimate of the velocity of the equatorial current of the North Atlantic; but the Admiralty chart to which he refers shows many instances of a velocity still greater; and whatever force produces the current must clearly be adequate to the production of the greatest velocity it attains. This, however, is of no consequence to my argument. The barometer decreases very steadily, regularly, and gradually, from the patch of permanent high pressure to the line; and the effect of the formation of this patch would therefore be equivalent—as I said before—to a difference of water-level of about four inches in 1,800 miles; a difference which could no more generate a current of ten miles a day than it could one of twenty; but as whatever effect it was capable of producing was produced, once for all, many ages ago, the consideration of it has no direct bearing on the currents of the present day.

I would, therefore, repeat that neither as permanently existing nor as changing with the seasons, neither in their continuance, nor in their formation, nor in their fluctuations, can the areas of high and low pressure, which Mr. Buchan has delineated, and which formed the subject of Mr. Johnston's first letter, produce an appreciable effect on the Ocean Currents; and that, since the Equatorial Currents in the several oceans follow the course of the Trade-winds, and are not affected by transitory differences of pressure which do not exist in the Trade-wind region, the movement of these differences of pressure where they do exist, cannot be considered as causing the current, or as necessary to its flow, though it may occasionally give it an increased velocity. But any effect so produced is due not to the mere existence or formation of a centre of low pressure, but to its *onward movement;* and to urge that this onward movement exercises an influence on the currents, is merely to urge, with respect to one not very important detail, the application of that principle which, in its widest sense, I have already maintained through a long chapter in my Physical Geography, and which Mr. Croll is now maintaining in the *Philosophical Magazine*—that the Ocean Currents are due entirely to the action of wind.

J. K. LAUGHTON

Royal Naval College, Portsmouth, Feb. 5

In reference to the exchange current found to exist between the Mediterranean and Atlantic, at the Straits of Gibraltar, it seems a matter for inquiry how far the rise of the ocean bed, just outside the Straits, is natural; and how far it may have been formed or increased by deposits left during the successive ages, by this undercurrent of out-set-water, from the Mediterranean Sea into the Atlantic Ocean. A. H.

Jan. 19

The Frost

HAVING seen notices in your journal about the severity of the late frost, I beg to state that its duration and severity have been most remarkable here, and unequalled, as far as my knowledge extends, for many years back. My instruments are standard ones, which have been recently compared at Kew, and placed in my garden quite detached from buildings, and facing the N.E. at 4ft. elevation. I append a table of the observations, which may be interesting to some of your readers:—

Dec. 1870.	Shade max.	Shade min.	Exposed min.	Jan. 1871.	Shade. max	Shade. min.	Exposed. min
20	47·8	30	30	1	27·5	19·8	18·2
21	30	22·8	22	2	26	24	24
22	26·8	15	15	3	33	21·5	21·5
23	29	1·5	0	4	31	14	13
24	24	−2	−3·5	5	39	23	23
25	28	+3	+3	6	42·2	31	31
26	33	24	23	7	45	30	29·5
27	31	24	23·5	8	40	28·3	28·3
28	32·2	27	27	9	40	25·3	25
29	32·8	10·5	10	10	40	28	28
30	31·6	15	14·5	11	36	30·5	29
31	32·8	15·2	14·3	12	35·8	20·5	20
				13	35·6	26·5	26

The frost was succeeded by a heavy gale of wind and a deluge of rain; in four days 2¼ inches fell, one inch being between 9 A.M. 17th, and 9 A.M. on the 18th. This, together with the melting of the snow, inundated the valley of the Medway round us for miles. The greatest cold I ever registered here was on January 4, 1867, being 5° below zero. The highest shade temperature I have recorded was 100°·5 on July 22, 1868, which was the hottest summer ever experienced.

Tunbridge G. H. FIELDING

Caves near St. Asaph

IT will interest archæologists to know that new caves are being opened by Mr. Townshend Mainwaring in the neighbourhood of St. Asaph, and that already we have much additional evidence brought to light as to the early inhabitants of that part of the country. In one which appears to run downward into the cliff at Carregwen, near Galltfænan, remains of various animals have been found in brown cave-earth, among them one which has been determined to be that of a reindeer, by Mr. Dawkins, who is further of opinion that it has been gnawed by a wolf or hyæna. This is very interesting, as the cave is high up in the face of a precipice, and with the present physical geography the larger animals could not get into that cave except by being carried there; so that we have here either cave-earth containing remains of such a remote antiquity that the gorge below has been considerably altered since its accumulation, or we have the ancient abode of carnivorous beasts able to carry the large animals into their den.

In Brysgill, Mr. Mainwaring has met with greater success. From the rubbish and tumble under the rock shelter outside the mouth of a large cave, he has obtained a fine bone scraper ground to a sharp edge, several flint flakes and bones of man, horse, ox, sheep, hog, &c. Inside the cave, immediately under the recent mould, there is a broken stalagmite floor, associated with which were human bones and the flint flakes, and cores. At about two feet below the broken stalagmite floor, the bones of a horse were found in undisturbed brown earth. Here we have evidently the home of some of our troglodytic ancestors who manufactured their flakes in the cave from flint which they may have procured from the drift not far off.

This is only one of a number of most promising looking caves to which Mr. Dawkins some time ago called attention, and it is to be hoped that, with so many residents in the neighbourhood interested in scientific investigation, we may have them all systematically explored, and not lose any bit of important evidence from the want of observation at the time of discovery.

T. McK. HUGHES

The Primary Colours

ONE more proof that violet is a primary. Place a hand prism between the eye and the sunlight so as to show the prismatic colours. Then hold a sheet of yellow glass between the prism and the light, and observe the result. The reds and yellows are scarcely altered, the greens are very greatly intensified, the blues and violets are altogether extinguished. If violet had really any red in it, the yellow glass, which does not stop the red rays, would change the violet to red, or would show at least some *trace* of red where the violet had been. Instead of this, the violet is totally stopped out, and the space which it occupied left dark. Wherever the secondary *pink* appears, this is changed to red by the stopping of the violet rays. The increased strength and brilliancy of the green shows clearly also the primary character of this colour. It is usually much weakened in the spectrum by mixture with the far-spreading violets; when this is removed it comes out in full splendour. I commend this little experiment to amateurs; it is simple and interesting. The same effect is produced by throwing the coloured spectrum on to a white wall, and holding the yellow glass between the prism and the wall.

Leicester, Feb. 20 FREDERICK T. MOTT

Californian Oaks

IN NATURE, No. 68, p. 313, you did me the honour to quote a paper of mine in reference to the edible qualities of some of the Californian oak acorns. You will, however, allow me to state that, though this is true of some species, such as *Quercus lobata* Nee, which was the one I chiefly referred to in the passage quoted, yet that the acorns of others have a decidedly injurious effect, or are inedible. For instance, it is very commonly believed by the *rancheros* that the acorns of *Q. Kelloggii* Newb. give rise among pigs to a peculiar disease of the kidneys, while the acorns of a new species from Southern Oregon—which I shall shortly describe in a work now in the press—(*Q. echinoides* mihi) are so very bitter that no animal but the black bear (*Ursus Americanus*) will eat them, and it only when pressed by hunger. On the other hand the acorns of *Quercus Orstediana* (mihi), another as yet undescribed species, are so nutritious, that though the species never grows to a greater size than a small shrub, the produce of forty or fifty such bushes will fatten a hog. Again, there is a difference of quality among the edible species. The "digger" Indian, who is quite a *connoisseur* in acorns, makes a difference; for while the interior tribes prefer those of *Q. lobata*, those living near the coast chiefly affect *Q. sonomensis* Benth. Though pigs fatten freely on the acorns of *Quercus Garryana* Dougl., and in California on those of its ally, *Q. Douglasii* Hook., yet I never knew the Indians either in Vancouver Island or in California eat the acorns of either species, while those of *Q. agrifolia* Nee, *Q. chrysolepis* Liebm., *Q. densiflora* Hook. and Arn., *Q. Sadleriana* mihi (nondescript species), &c., are not, so far as I am aware, eaten by any animal but squirrels. The fruit of *Castanopsis chrysophylla* Doug., a plant allied to the oaks and chestnuts, is, however, in great favour with the black bear. I have eaten the acorns cooked in the manner described in the extract, and—I suppose in common with other naturalists in the less explored parts of North-west America—have been forced by hunger to search for the acorns which *el carpentero* (*Melanerpes torquatus*) stores away for its use in the spongy bark of *Torreya*, *Sequoia*, *Pinus*, and various other trees, yet notwithstanding the sauce which famine gave to my appetite, I must confess that they were by no means palatable. This may, however, have been prejudice, for the Ancient Britons—who were by no means savages in the ordinary acceptation of the term—ate the acorns of *Quercus robur*, the common oak of this country. How they cooked them we are not informed. I presume, however, that it was not in so *recherché* a style as practised by some aboriginal friends of Mr. Paul Kane, the artist—a full description of which those curious in North American Indian *cuisine* will find in that gentleman's book descriptive of his journey across the American continent. Edinburgh, Feb. 20

THE ECLIPSE PHOTOGRAPHS

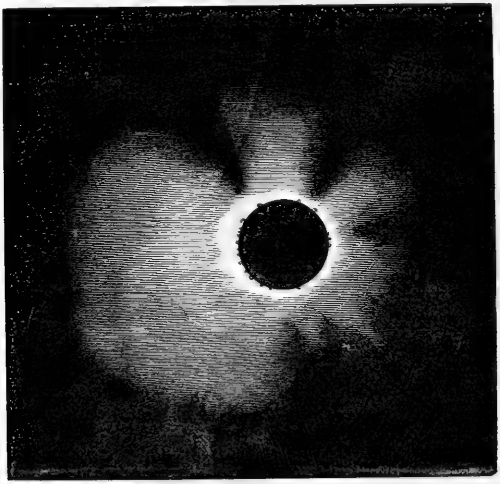
THE accompanying woodcut is a copy of a drawing made from the negative No. 5, taken at Syracuse during the Eclipse of the sun on Dec. 22 last. When viewed by transmitted light, the negative shows chiefly the portions indicated by the unshaded parts, and the red prominences; some parts of the first light shade can be seen, but the outer rays are altogether invisible. When, however, the plate is viewed by reflected light, the whole of the detail is distinctly seen. The negative was the last one taken; four others were exposed for the corona, but owing to the presence of cloud very little detail is visible.

It will be noticed that there is more of the corona shown on the west side of the moon than on the east, north, or south. This feature is shown on all the plates, so that there can be no question that there was more coronal light on the west side of the moon than at the other points. In explanation of the great display of the outer rays (I use the term *rays* for want of a better—perhaps *outer light* would be more correct, for there is no indication of lines or rays on any of the plates), I had supposed that the east side might have been partially covered with cloud; but in conversation with Prof. Eastman I found that he was observing for the reappearance of the sun, and he is quite certain that there was no cloud at the time the photograph was taken—that is, at about thirteen seconds from the end of totality. Mr. Fryer also is equally certain that there was no cloud. The plate was exposed eight seconds. It will be noticed also that the prominences are more numerous on the side where the corona is brightest.

Various opinions have been expressed as to the quality of the light of the corona. The effect we saw was that of moonlight, but not of the *full* moon, excepting the brilliant light close to the moon's limb, which is equal to the brightest moonlight, and I think its action on the sensitive plate confirms this opinion.

A point of much interest to be noticed is, that the light of the corona had been considered to be much less active than it really is; eight seconds were sufficient to produce on the plate an effect of light extending beyond the moon's limb, at least one and a half millions of miles.

I leave it to others to account for the cause of the great gaps or rifts in the corona; also their identity in position with those shown in the photograph taken by the American photographers at Cadiz. The identity of one of the rifts



THE LATE ECLIPSE, AS PHOTOGRAPHED AT SYRACUSE

is absolutely fixed by the two prominences between which it appears in the photographs, and this one gives the relative places of the others.

When the two photographs are compared, there is an apparent difference in the places of the rifts with respect to their angular position on the moon's circumference. How this difference arises I am not prepared to say, as I have no information as to how the American picture was taken, and there is no mark on the transparency which has been lent to me by Prof. Young, to indicate the north point. In the engraving from my photograph the top is the north.

It is perhaps necessary to say that it is quite impossible to represent in an engraving on wood the delicate detail of the corona. The cut fairly gives the main features, but it is *hard* when compared with the original; the contrast should not be so great; the ground should not be perfectly black; and the effect should not be produced by *lines*. No woodcut has ever yet accurately represented the phenomena of the eclipsed sun.

When the photograph No. 5 is combined in the stereoscope with the one taken about one minute earlier, stereoscopic relief is produced—the corona is distinctly seen beyond the moon. It may be thought that this is merely the effect of contrast, but I believe it is really due to the change in the position of the moon. No such relief is seen when two copies of the same photograph are combined stereoscopically.

In order to see the woodcut with the best effect, it should be placed at a few feet distance from the observer, so as to lose all trace of the lines of the engraving; the effect is then very accurately given of the corona as seen by the unaided eye.

A. BROTHERS

THE LATE EAST INDIA COMPANY'S MUSEUM—A ZOOLOGIST'S GRIEVANCE

THE late East India Company in their former palace in Leadenhall Street were in possession of a valuable Zoological Museum. It contained specimens in all departments of science, received from the Company's Oriental dominions. These had been contributed by public servants, attached as naturalists to various missions, or had been given by gentlemen of the civil and military services to the Court of Directors. Amongst the contributors to the East India Museum, it will be sufficient to mention the names of Dr. F. Buchanan Hamilton, Dr. Horsfield, Sir T. Stamford Raffles, Col. Sykes, Dr. Wallich, Mr. M'Clelland, Dr. Falconer, Mr. Griffith, and Mr. Hodgson, to prove that the collection was one of no ordinary merit. The Zoological importance of the East India Company's Museum was further augmented by the preparation and publication by, or under the superintendence of, the late Dr. Horsfield, of several catalogues. Of these may be particularly mentioned that of the Mammalia, published in 1851, and that of the Birds in 1854 and 1858, the second part of which bears likewise the name of Mr. Frederick Moore, then assistant-keeper of the Company's Museum, as joint author, on its title-page.

When the East India Company became extinct, and the premises in Leadenhall Street were vacated, the Museum was removed to Fife House, Whitehall, but was very imperfectly exhibited there, a large portion of the contents (the more bulky specimens in particular) being kept stowed away in boxes. When naturalists who wanted to consult specimens remonstrated at their inaccessibility, they were told that this was a mere temporary arrangement, and that when the magnificent buildings of the new India Office were completed, special accommodation would be assigned to the Museum, and there would be ample space for everything. At length the time arrived. The new India Office, with its suites of *salons*, assembly rooms, waiting rooms, and apartments of every description, was finished and opened. Fife House was demolished, and everything that it contained was removed to the new establishment. But when space was required for the Museum it was discovered that the only rooms assigned to this purpose were three or four chambers in the uppermost story, which would not contain a tenth part of the collection. Dr. Forbes Watson, the present chief of this department, has thought it right to devote these to the exhibition of a fine series of specimens illustrative of the arts and manufactures of British India, and we are by no means disposed to find fault with his decision on this subject. But it is the duty of the Government, we maintain, either to provide proper space for the Zoological collections also in the New India Office, or to transfer them to some other Institution, where they may be at least accessible to the scientific student. These Zoological collections contain a large number of typical specimens, without reference to which it is impossible in many cases to ascertain the identity of the species. Some of these typical specimens have, we believe, been handed over to the British Museum, but a number of them still remain in the collection, packed away, we are told, in the same cases in which they were originally removed from Leadenhall Street. This is, we maintain, a great and crying scandal, though as only a few working Zoologists are injured thereby, it is difficult to excite popular feeling upon the subject. In taking over the goods and chattels of the former Company, the India Office must certainly be held to have accepted the corresponding liabilities. Amongst these, it cannot be denied, was that of keeping, at least safe from destruction and in a state accessible to the scientific student, the specimens which the servants of the former Company amassed at such an expenditure of time and toil. If, as we are told, the new India Office is already so short of space that it is not possible to find room for them within its precincts, it is very simple to obtain the necessary accommodation elsewhere. We have good reason to know that Naturalists working on various branches of Indian Zoology are frequently brought to a standstill by the impossibility of access to this important collection, and we trust, therefore, that some steps will be taken to remedy the evil

P. L. S.

THE METAMORPHOSES OF INSECTS*

THIS very handsomely got-up volume is illustrated by 40 full-page engravings, many of which are exquisite landscapes as well as representations of insects in their various stages; and by about 200 excellent woodcuts in the text, from which we have selected a few specimens as samples of the rest. The subject of insect transformations presents us with so many curious examples of instinct, and such strange eccentricities of structure and habits, as to be especially adapted to attract the attention of the young, and to lead them to study this most fascinating branch of Natural History. The name of M. Emile Blanchard, and the high scientific reputation of Prof. Duncan, are a sufficient guarantee that the facts are accurately stated. In the introductory portion of the work, the main features of the external structure and internal anatomy of insects are exhibited by such large and clear illustrations as to be easily comprehended, the changes in the nervous system, from the larva to the perfect insect, being particularly well shown. The nature of metamorphosis and its different kinds are then explained, and a series of chapters is devoted to each order of insects, beginning with the Lepidoptera and ending with the Crustacea.

Among the more remarkable forms in the first-named order are the Psychidæ, small moths the females of which are not only without wings, but have neither legs nor antennæ. The female *Psyche* is, in fact, a mere helpless egg-bag, which never quits the case or covering in which it was bred. The males are small delicate moths with bodies covered with long silken hairs, and with dusky semi-transparent wings. The larvæ live in cases made of silk or vegetable tissue, bits of straw, stick, or leaves, and they carry these cases just as snails do their shells.

The ravages of the Tineidæ and the curious cases of *Coleophora* and *Gelechia* are illustrated by figures after Stainton; while the cut on p. 331 represents the beautiful pink or violet net-work cocoons in which some Brazilian species suspend themselves by slender threads.

The parasitic Hymenoptera forming the families Ichneumonidæ, Chalcididæ, and Proctotrupidæ are well described, and a quotation from this chapter will exhibit the style in which the book is written :—

"These parasites are very pretty and elegantly-formed insects when in the adult form, and are gifted with great agility and restlessness; but in their early condition they cannot move, having no locomotive organs, and their structures are so soft that they are destroyed with the greatest ease. The larvæ look like worms or maggots, and do not attain a great perfection of development during their growth. All the parasites seek out a caterpillar, a larva, or an insect which suits their purpose, in order to lay an egg within its body. The larva which is born from this egg is nourished by the blood and fat of the victim, whose vital organs it does not touch or injure in any way; for were it to die, the parasite would come to an end also. It is only when the larva is nearly full grown, and is about to undergo its metamorphosis into a pupa, that it appears to know that the life of the victim is not likely to be of much further use. It then devours the internal organs of the unfortunate insect, and undergoes its transformation. The skin of the victim protects some of the pupæ of its destroyers after all the inside has been eaten. Nearly all, if not quite all, insects are subject to the attacks of parasitic Hymenoptera. Fine, smooth, and brightly coloured caterpillars often have a black spot upon their skin, and this is the healed wound of the ovipositor of one of the parasites. Sooner or later the creature is sure to die, and

* "The Transformations or Metamorphoses of Insects (Insecta, Myriapoda, Arachnida, and Crustacea)." Being an adaptation for English readers of M. Emile Blanchard's "Metamorphoses, Mœurs, et Instincts des Insectes." By P. Martin Duncan, F.R.S., Professor of Geology in King's College, London. (Cassell, Petter, and Galpin)

it never reaches the stage of growth when it can lay eggs or reproduce its kind, for before this time the growing larvæ within destroy it, as it were, by slow consumption. Some affected caterpillars die soon, others nearly reach their full growth, and a few undergo their transformation into the chrysalis state before death. It is, therefore, not an uncommon thing for a butterfly-collector, who hopes to see a fine moth disengage itself from its pupal covering, to be disappointed by the appearance of several little parasitic Hymenoptera that had been living within the chrysalis he has been keeping."

One of the most curious recent discoveries among beetles is that which was published by Schiödte, in 1864, of viviparous Staphylinidæ. These are about the tenth of an inch long, and are found in the nests of the *Termites* of Brazil. They are distinguished by the swollen development of the abdomen, which is carried in a most peculiar manner, being turned up and allowed to rest on the back of the insect. The enormous distension of this part of the body is due to the fact that the beetles do not lay eggs, but produce living larvæ, and they are the only beetles that do so. It is supposed that the hairs which

FIG. 1.—THE CHRYSALIS AND THE FEMALE PERFECT INSECT OF *Psyche graminella*.

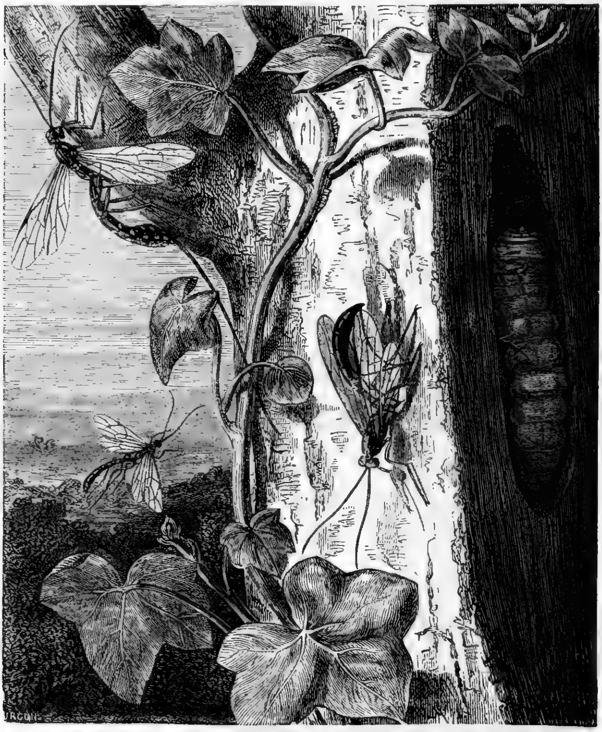


FIG. 2.—ICHNEUMONS

Ephialtes manifestator. The male is flying on the left, and the female is introducing an egg into the body of a larva. Another *Ephialtes, Rhyssa persuasoria,* a female, is on the branch to the left hand.

cover some parts of the abdomen are furnished with a peculiar secretion that is liked by the white ants among which they live.

The extraordinary economy of many of the Diptera or flies is exhibited in a variety of beautiful cuts, one of the best of which represents the metamorphoses of *Stratiomys chameleo.* This fly frequents flowers in order to prey upon other insects, but its larva lives in stagnant water, and is a long, hard-skinned creature, whose small head is furnished with two minute hook-like mandibles. The terminal segments of the body are gradually narrowed, and can be elongated like a sliding telescope, and the slender extremity terminates in two small orifices crowned with hairs. This larva swims about in shallow water, and when it wants to breathe it sticks up the end of its body and respires through the two small holes at the apex. When the larva is mature it floats on the surface, the pupa being formed within the skin, which serves at once as a cocoon and as a boat, from which in due time the brightly-coloured and active fly escapes to its aërial existence.

In the last chapter a short but clear account is given of the recent discoveries as to the metamorphoses of Crustacea, from the works of Spence Bate, Fritz Müller, Darwin, and others.

In the original work reference is chiefly made to common French or Continental insects, some of which are natives of our own country, while many are not found here. In adapting the work for English readers, it would have been well to have stated in every case whether the insect mentioned was an English one. The great carpenter bee (*Xylocopa violacea*), for example, is described as "not uncommon;" but the reader is not told that, although common in France, it is unknown in England. More simple and familiar language might also have been occasionally used; but these are small defects in so useful and attractive a work, which is just the thing for a present to an intelligent and inquiring country schoolboy.

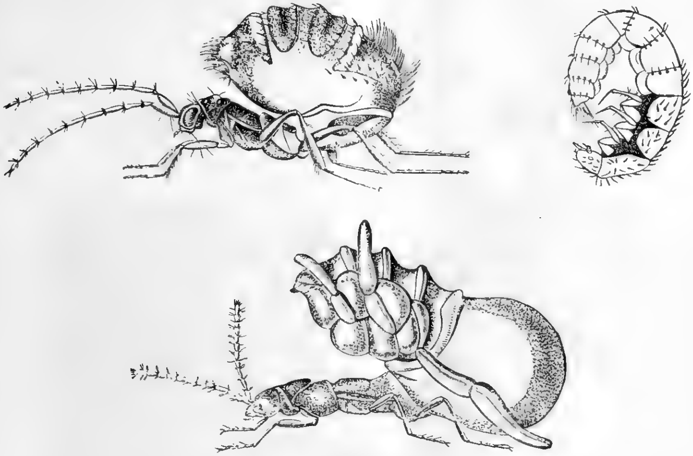

FIG. 3.—VIVIPAROUS *Staphylinidæ*. (After Schiödte.)
Corotoca melantho and larva. *Spiractha Eurymedusa.*
The upper figures are those of *Corotoca*. The turning up of the hinder parts of the body is very evident in the engraving.

ALFRED R. WALLACE

NOTES

WE understand that the Home Secretary has intimated to Dr. Lyon Playfair, member for the Edinburgh University, that he will submit the name of Mr. Geikie, F.R.S., to the Queen as first professor in the new Chair of Geology in that university. This has been done at the express recommendation of Sir Roderick Murchison, who, as already announced, has given the sum of 6,000*l.* to found the chair. In spite of her great mineral wealth, Scotland has no school of applied science like the State-supported establishments in London and Dublin. It is matter for congratulation, therefore, that the first appointment to the first Chair of Geology established in Scotland should have been given to one whose position as director of the Geological Survey in that part of the United Kingdom will enable him to act effectively in the teaching of the practical applications of geology.

THE trustees of the British Museum have wisely not departed from precedent in appointing Mr. W. Carruthers, F.L.S., F.G.S., to the Keepership of the department of Botany, in the room of Mr. J. J. Bennett, lately resigned. Mr. Carruthers has been Mr. Bennett's senior assistant for eleven years, during which time he has done much to render the extensive botanical collections of the Museum readily accessible and useful to the public. Mr. Carruthers is widely known for his numerous and important papers on Vegetable Palæontology, in which he has greatly contributed to a knowledge of the structure and affinities of extinct forms of vegetation.

ACCORDING to a constant practice strictly adhered to for almost two centuries, at the first sitting in January of the French Académie des Sciences, the vice-president for the preceding year fills the office of president, and keeps it for twelve months. But M. Coste having left Paris before the siege, the change in the presidency could not take place. The members present, to the number of thirty-one, elected the vice-president for 1871, who will be president for 1872. M. Faye was elected and proclaimed by M. Lionville, who was then in office. The election took place with the thermometer at -6° C. No fire was allowed to be lighted, in consequence of the scarcity of fuel.

DR. W. B. CARPENTER recently delivered his Lecture, "On the Temperature and Life of the Deep Sea," at the Hulme Town Hall, Manchester, and it is reprinted as one of the penny series of "Science Lectures for the People," to which we recently referred in terms of commendation.

THE report of the commissioners appointed by the Lord-Lieutenant and General Governor of Ireland in October 1868 to inquire into and report on the Artificial Cultivation and Propagation of Oysters, and the methods used in some parts of Great Britain and France for these purposes, has just been printed. It forms an octavo blue-book of nearly 200 pages, and is illustrated with woodcuts and ten plates. We hope in a future number to give a short notice of the recommendations offered in this report.

WE understand that the library of the late Dr. Matthiessen, including a large selection of valuable works on chemistry and physics, is to be sold to-morrow, at Puttick and Simpson's Auction Rooms, in Leicester Square.

PROF. KARL KOCH, of Berlin, proposes the establishment in that city of a Dendrological Garden, to be specially devoted to the cultivation of species and varieties of all kinds of foreign trees and shrubs. Plans of the proposed garden were shown at the last meeting of the Council of the Royal Horticultural Society.

M. JANSSEN is now at Bordeaux preparing his memoir on the Eclipse, for presentation to the French Académie des Sciences.

THE Astronomer Royal for Ireland has just published the first part of a series of astronomical observations and researches made at Dunsink, the Observatory of Trinity College, Dublin. This part contains results of observations made with the South Refractor from June 1868, to October 1869, and consists of 88 quarto pages and three plates, printed at the expense of the Board of Trinity College. We purpose, in an early number, to give a short account of the College Observatory and of the equatorial erected for the fine $11\frac{3}{4}$in. object glass presented by Sir James South to the college.

THE following is a list of the third series of lectures arranged by the Sunday Lecture Society to be delivered at St. George's Hall, Langham Place, on Sunday afternoons, at half-past three o'clock:—Feb. 26—Mr. Moncure D. Conway, on "The Past and Present of New England: its Early History, Physical Features, Literary and Religious Development, and Sketches of leading thinkers—Emerson, Theodore Parker, &c." March 5—Jon A. Hjaltalin, of Iceland, on "Iceland: its Physical Features, Volcanoes, Hot Springs, &c., the Manners and Customs of its Inhabitants." March 12—W. G. Clark, M.A., Vice-Master of Trinity College, and late Public Orator, Cambridge, on "Protestantism." March 19—J. Norman Lockyer, F.R.S., on "The Total Eclipse of Dec. 22." March 26—T. Spencer Cobbold, M.D., F.R.S., on "The General Structure and Development of Ferns." April 2—Edward Maitland, B.A., on "Jewish Literature and Modern Education; or the Use and Mis-use of the Bible in the School-room." April 16—W. K. Clifford, M.A., on "The History of the Sun: an Explanation of Laplace's Nebular Hypothesis, and of Recent Controversies in regard to the Time which can be allowed for the Evolution of Life." April 23—Prof. J. S. Blackie, on "War; its Causes, Character, and Consequences."

AT the sitting of the 23rd January, the French Academy learned the death of M. H. Regnault, son to M. Regnault, the learned member of the section for physics. This young man, a painter of rising fame, had been killed when attacking the woods of Buzenval on the 19th of the same month. A deliberation of the assembly was taken to congratulate M. Victor Regnault, the father, then at Geneva. The body having been found was buried in the Père La Chaise before a deputation from the Académie des Sciences, Académie des Beaux Arts, and Académie Française. The proceedings were recorded in the *Comptes Rendus.*

DURING the week ending 18th February upwards of 3,500 British objects, consisting of sculpture, pottery, woollens, and educational works and appliances, were delivered at the buildings of the International Exhibition of 1871, besides foreign objects from Bavaria, Belgium, and Saxony.

WE are informed that public meetings on the subject of Science and Art Education have recently been held in many places in the West of England. The well-known Royal Albert Museum at Exeter, with its Science and Art classes, museum, and free library, has done much towards attracting attention to the value of scientific knowledge in this part of England. The Plympton Grammar School, which has just been reorganised under a new scheme, will include the teaching of chemistry and drawing as a regular part of the school course.

PROF. PHILLIPS is busily engaged at Oxford upon his new work on the "Physical Geography and Geology of the Thames Valley." This volume will contain numerous plates of fossils, illustrative of the various beds to be met with in the district, all of which are drawn by the learned Professor himself. In addition to these the numerous drawings of the magnificent series of Ceteosaurian remains lately acquired by the Oxford Museum will cause this volume to be eagerly looked forward to by every geologist and palæontologist

THE offer to build a Museum at Hereford in connection with the Woolhope Naturalists' Field Club has been very gratefully accepted by the Corporation of that town, and there is every prospect of Mr. Rankine's generous scheme being fully carried out.

THE British Museum has lately acquired two fine specimens of the most gigantic of known crabs. This species measures 10 feet between the tips of the claws, but has a comparatively small body, triangular in shape, somewhat convex. The claws are thin, and about 6 feet in length, including the pincers. Its habitat is Japan, where it is, we believe, eaten for food, and it seems strange that specimens should be so scarce in Europe. It was described and figured by Kæmpfer, in 1763, in his account of Japan, and is now named *Macrochira Kæmpferi* (Dettaan) in commemoration of that eminent naturalist. One specimen has also been acquired for the Edinburgh Museum.

AT the sitting of the 30th January the French Academy learned the death of M. Gustav Lambert, who was engaged in preparing an expedition to the North Pole when war broke out, and who had been badly wounded at Montrelaut when fighting at the head of a company of National Guards which he commanded. M. Élie de Beaumont read a memoir sent four years ago by the enterprising intended explorer. Before leaving Paris for his last fight, he had sent to the Défense Nationale a memoir on the means of communication between Paris and the Provinces. This memoir will be published when peace shall be restored.

THE large series of fossils in the Oxford Museum is in process of re-arrangement, and the space formerly occupied by the Physical Science Apparatus, removed into the Physical Laboratory, is now devoted to large collections of fossils hitherto undisplayed for want of room. Chief among these is to be noticed the magnificent series of Ceteosaurian remains from Enslow Bridge, which is the finest collection of gigantic reptilian remains to be seen in any museum in the world. The greatest care and ingenuity have been displayed in reconstructing these immense bones, many 4ft. or 5ft. long, from the broken and fragmentary state in which they were originally found.

THE splendid meteor noticed by Mr. Wilson, in our last number, as having been observed at Rugby, was also very clearly seen in the neighbourhood of Worcester a few minutes past nine o'clock. It is described as falling towards the S.W., and bursting like a rocket, when it left a trail of light behind it for some time after its disappearance. No audible explosion was heard. The atmosphere was clear, and there were only a few clouds in the sky.

M. BIENAYMÉ has published in the *Comptes Rendus* a rectification of a catalogue of the articles written by Cauchy, the celebrated mathematician, formerly a member of the French Institute. Some of the articles attributed to Cauchy were written by Cournot. This list is of some importance, as Cauchy's works are under publication at the expense of the French Academy, according to a vote which was taken a few months before the war broke out.

WE have received the first report of the Cheltenham College Natural History Society, which we commend to the notice of similar youthful societies, for the modest earnestness that pervades it. The achievements of the society for the first year of its existence are summed up as follows :—"Botany—Decidedly well worked; best point of the Society. Entomology—Also well worked; sadly deficient in *Coleoptera*. Zoology—Practically reduced to Ornithology; so far, so good. Geology—Little attempted; less done." In so rich and interesting a county, geologically speaking, as Gloucestershire, we hope the Society will have next year a very different tale to tell. We notice that in order to encourage the pursuit, the Council offers a prize for the best original collection of local fossils; but trust this will not tend to promote the habit of collecting for mere collecting's sake—the bane of young naturalists. From the general tone of the pursuit of Natural History in the College, however, we hope for better things. It is interesting to find that such subjects are discussed at their meetings as the theories respecting the Aurora, and the causes of the November Showers of Meteors; and although the papers on "The Flowers of Virgil's Eclogues" and "The Flowers of Virgil's Georgics" are stated to have been "scarcely suited to the requirements of a scientific meeting," we doubt not they will have invested the old poems with a new interest in the eyes of both the writer and his hearers. Some of the papers are, as might be expected, crude and inaccurate; the one on "Butterflies at Home and Abroad" requires revision; and the statement that the Killarney bristle-fern, *Trichomanes radicans*, has been gathered by one of the members in Cornwall, must be received with caution. Although this would not be "the only spot in England where that fern has yet been found" (there being old records of its having been gathered in Derbyshire, and it having recently been unquestionably met with in North Wales), and there is no inherent improbability in its growing in Cornwall, yet the specimen stated to have been gathered "not half an inch high," can scarcely have been satisfactorily determined to be this rare fern. Seedling ferns of all kinds are extremely difficult to distinguish, and when growing in damp places, frequently simulate the filmy appearance of the Irish fern. We shall watch with great interest the progress of the Cheltenham College Natural History Society.

DR. C. L. SPIEGEL'S "Cultur-historische Tafeln," published at St. Petersburg, gives in parallel columns the men distinguished in each epoch from the earliest times to the present in politics and war, technical or mechanical discoveries, medicine, divinity, natural science and mathematics, philosophy, law, history, belles-lettres, and the fine arts; in Greece, Italy, Spain and Portugal, France, Great Britain, America, Sweden, Norway and Denmark, Holland, Germany, Russia and Turkey, Asia and Africa. It is printed in German.

THE register taken by M. Renan at Montsouris Observatory shows that the minimum temperature in December was $-11{\cdot}7°$ C. in the garden, and $-12{\cdot}8°$ on the roof. This minimum is not exceptionally low for the district. The feature of the temperature for the month was not so much the number of degrees under freezing-point as the continuity of cold. Nine days only exhibited a mean temperature above the freezing-point. The temperature for the whole month was about 8° F. lower than the mean temperature of Paris for December.

WILLKOMM AND LANGE'S "Prodromus Floræ Hispanicæ," published at Stuttgart, is now brought down to the third part of the second volume, including the natural orders to the end of the Gamopetalæ or Corolliflοræ.

FREIHERR LUDWIG VON HOHENBUHEL-HEUFLER has reprinted from the Proceedings of the Zoological and Botanical Society of Vienna an interesting contribution to botanical history, "Franz von Mygind, der Freund Jacquins." Mygind was born at Broust, in Jutland, in 1710, and after his education at the University of Copenhagen, and a short stay at St. Petersburg, took up his residence at Vienna, and devoted his attention to botany. He speedily became an intimate friend of Jacquin's, and corresponded with the most eminent scientific men of the day, including Priestley, Sir Joseph Banks, L'Héritier, and Gmelin. He did great service in investigating the flora of Austria, paying the expense of two Alpine expeditions by Wulfen. He died in 1789.

THE MICROSCOPE

IMPROVEMENTS IN THE LENSES OF MICROSCOPES

FOR some time, people in England have been content to let the improvement of the optical powers of the microscope remain entirely in the hands of the makers, believing, apparently, that Mr. Lister had effected all in his suggestions and improvements that could be desired. Dr. Royston Pigott, an able mathematician, formerly Fellow of St. Peter's College, Cambridge, and a Doctor of Medicine of that University, was not, however, inclined to look at the matter in this way, and for many years has been working and experimenting with a view, first, to test the accuracy of our best object-glasses, and, secondly, to suggest means for their improvement. It should be remembered that Oberhauser, Nachet, and especially Hartnack, on the Continent, not satisfied with the old system of combinations for object-glasses, and not having the benefit of Lister's researches, have made excellent objectives on a totally different system, and during the last few years the last-named maker has carried his system of "immersion lenses" to such a point of excellence as really to surpass the best glasses on Lister's system, in definition, penetration, working distance, and illumination. Those who do not admit the excellence of these objectives, which are now used by nearly all German histologists, have probably seen older glasses, made at a time when Hartnack had not reached his best. It is worth stating, now that the Parisian opticians are inaccessible, that Gundlach of Berlin has succeeded in making excellent glasses of high power at astonishingly small prices, some of his 1-12ths and 1-16ths immersion 1-16ths (so-called), being admirable in their performance. They are not, however, equal to Hartnack's glasses, which, though costing far less than what similar English glasses cost, yet are more expensive than Gundlach's. It is only fair to all parties concerned to state that the terms 1-8th, 1-12th, 1-16th, &c., as now applied to an object-glass, appear to have no definite meaning, but depend on the caprice of the maker, since the magnifying power of glasses, with the same fraction assigned to them, differs enormously.

To return to Dr. Royston Pigott. He found the usual means of testing an object-glass by trying if it gave some particular appearance with a "test object," such as the Podura-scale, very unsatisfactory, since we have no certainty to begin with as to what is the true appearance of such an object. He therefore examined minute images of objects of which he knew the true form, such as a watch-face or thermometer-scale, forming these images by aid of mercurial globules and the condenser properly adjusted below the microscope-field. By this means he has found that object-glasses corrected so as to show dark, sharply marked spines (like !!!) on the Podura-scale—a favourite test-object with our microscope-makers—give false, blurred, and distorted appearances with his known images, and on making such corrections of the objective as to show the known images in their true form, he finds that the Podura-scale, examined with the corrected objective, is not really marked at all, as supposed, but is beset with a series of bead-markings, which by intersection, when improperly defined, give the curious appearance like notes of exclamation. This important discovery of the falsity of our high powers (1-8th to 1-16th), has led Dr. Royston Pigott to pay more attention to the lower powers, and he finds that though you may not get so much actual amplification, you yet get a truer effect, and greater clearness of detail, by employing very carefully made low powers (1-2nd to 1-5th) and increasing the magnifying power at the other end of the microscope, *i.e.*, the eye-piece. We have in this way seen the beaded structure of the scales of Podura more satisfactorily than with very high objectives even when corrected so far as they would admit, and we may say the same of some Diatom-valves *e.g.*, *Pl. formosum*. It would be most important to know how far such a change of combination would be useful in histological work.

The general upshot of Dr. Royston Pigott's investigations appears to be that it is desirable to shift the burden hitherto cast almost wholly upon the objective, to the other parts of the instrument. We should be content with an objective as high as a fifth, or even less. A very deep eye-piece is to be used; and to correct residuary aberrations of the objective, and at the same time amplify, Dr. Pigott has introduced an important adjustable combination *between the eye-piece and the object-glass*. There seems to be considerable reason for the step proposed by Dr. Royston Pigott. Just as great results were obtained in passing from the single lens or combination to the compound microscope of eye-piece and objective, so by adding distinct integral factors to these two, such as Dr. Pigott's "aplanatic searcher," we may obtain excellences quite impossible by any amount of attention bestowed on the objective alone, or only with difficulty reached by long labour, leading to very high price for high powers.

Dr. Pigott has, during the past year, published some account of his researches in the *Quarterly Journal of Microscopical Science*, and has communicated papers to the Royal Society, one of which is about to appear in the Philosophical Transactions.

Naturally at first the makers in London and the Microscopical Society were sorely tried by Dr. Pigott's exposure of the Podura-scale, but we hear, as one good result already obtained, that Messrs. Powell and Lealand have constructed a new 1-8th both dry and immersion, with great care, which is declared to be the best glass yet made. It has been proposed to form a committee for the purpose of examining carefully as to penetration, definition, and angular aperture, the best glasses of our English makers, the best American glasses, and the best of Hartnack's, Gundlach's, and others; the glasses being mounted similarly, with private marks only for recognition, so as to prevent all possibility of prejudice on the part of the committee. Were this done, the result, whichever way it tended, would be eminently satisfactory. Of this the writer is sure, that many persons—even eminent microscopists—have made up their minds about the qualities of foreign objectives, without having seen any, or only very poor examples, and then when a really fair specimen of such a glass is placed before them, they exclaim with astonishment "Why this is the finest glass I have ever seen." We shall be glad to receive suggestions or assistance, in carrying out the proposed comparison of objectives. Dr. Royston Pigott has expressed his willingness to aid in such an undertaking.

E. R. L.

REPORT ON DEEP-SEA RESEARCHES

Carried on during the months of July, August, and September, 1870, in H.M. Surveying Ship "Porcupine" *

BY W. B. CARPENTER, M.D., F.R.S., AND J. GWYN JEFFREYS, F.R.S.

THE equipment of the *Porcupine* for the previous Expedition had been found so complete and satisfactory, that nothing more was considered necessary to prepare her for the work of the present season than the overhauling of her gear, and the manufacture of new dredges, sieves, and other apparatus, on the patterns of those which had already proved most serviceable. We had the advantage of the same excellent commander, now promoted to the rank of staff-captain, with his able staff of officers; and we would take this opportunity of again expressing our deep sense of obligation to them all for their hearty co-operation in our scientific work, and for the unvarying personal kindness by which our voyage was rendered a most agreeable one. A considerable part of the crew, also, consisted of the same steady and experienced men. The Meteorological Department supplied eight of the protected Miller-Casella thermometers, including the two with the performance of which we had been so thoroughly satisfied last year; and we usually employed one of these in conjunction with one that had not been used in the previous Expedition.

At the request of the Committee, Mr. Siemens undertook to devise an apparatus for testing the depth of sea-water to which light, or at least the actinic rays, can penetrate. The foundation of the apparatus which he constructed for this purpose is a horizontal wheel with three radii, each of them carrying a glass tube in which a piece of sensitised paper is sealed up. The rotation of this wheel round a vertical axis brings each of the tubes in succession out of a dark chamber in which it ordinarily lies, exposes it to light in an uncovered space, and then carries it into darkness again. This movement is produced by a spring; but it is regulated by a detent that project from the keeper of an electro-magnet, which is made and unmade by the completion or breaking of a circuit that connects it with a galvanic battery. When the magnet is made, it lifts the keeper with its projecting detent; and this allows the wheel to be carried by the spring through one-sixth of its rotation, whereby the first of the tubes is brought out into the open space. There it remains until the circuit is broken, whereby the magnet is unmade; the keeper then falls, and the wheel is allowed to move through another sixth

* Extracted from the Proceedings of the Royal Society.

of a rotation, so as to carry on the tube into the dark chamber. A repetition of the making and unmaking of the magnet brings out the second tube, and shuts it up again; and another repetition does the like with the third tube. This apparatus, with a deep-sea lead attached to it, is suspended by an insulating cable that contains the wires whereby it is connected with the battery in the vessel. Being lowered down to any desired depth, the circuit is completed, the magnet made, and one of the tubes exposed for as long a time as may be wished; the circuit is then broken, the magnet unmade, and the tube shut up again. The second tube may be exposed for a longer time in the same place, or the apparatus may be lowered to a greater depth, at which the experiment may be repeated; and the third tube may then be dealt with in like manner.—The committee having been satisfied with the performance of Mr. Siemens' apparatus, it had been arranged that trial should be made of it, and also of his Differential Thermometer, now provided with an improved Galvanometer; and he had undertaken to send out a qualified assistant to take charge of these instruments during the Mediterranean Cruise. The declaration of war between France and Germany, however, unfortunately interfered with this arrangement; the assistant (a German) being recalled to his own country, and no other competent person being available on a short notice. Under these circumstances it was thought better that the Differential Thermometer should not be sent out; but it was hoped that such a trial might be given to the Photometric Apparatus as should at any rate determine whether satisfactory results might be anticipated from its use, or whether any modifications in its construction might be needed. The apparatus was sent out to Gibraltar under charge of Dr. Carpenter, and was got into working order by his son and himself in Gibraltar Harbour. It proved, however, that the action of sea-water on the bearings,—increased as this was by the galvanic current arising out of the contact of iron and brass in them,—so embarrassed its mechanical arrangements, that no fair trial could be made of its photometric efficiency. But the experiment served the important purpose of showing the weak points of the apparatus; and neither Mr. Siemens nor Dr. Carpenter entertains any doubt that it may be so reconstructed as to answer the purpose for which it was devised.

The work of this year's Expedition was divided, according to the plan originally marked out, into two Cruises: the First to examine the Deep-sea bottom between Falmouth and Gibraltar; the Second to make the like examination of the western basin of the Mediterranean between Gibraltar and Malta, and to determine its Physical and Biological relations to the Atlantic,—with special reference to the Gibraltar Current. The First Cruise was under the scientific direction of Mr. Gwyn Jeffreys, who was accompanied by a young Swedish naturalist, Mr. Josua Lindahl, of the University of Lund, as Zoological Assistant; whilst Mr. W. L. Carpenter, as before, took charge of the Chemical department,—his special work, on this occasion, being the determination, by volumetric analysis, of the proportion of chlorine in samples of Atlantic water taken from the surface, the bottom, and from intermediate depths, so as to serve as a basis of comparison with similar determinations of Mediterranean water. In the Second Cruise it had been arranged that Dr. Carpenter and Prof. Wyville Thomson should co-operate as before; but the latter being unfortunately prevented by serious illness from taking part in it, the whole charge of this Cruise rested with Dr. Carpenter. He was fortunately able to retain the assistance of Mr. Lindahl; and the chemical work was continued (as in the Third Cruise last year) by Mr. P. H. Carpenter; Mr. Laughrin throughout acted as dredger and sifter.

[For the exceedingly interesting and valuable zoological details of the various dredging-hauls, we must refer our readers to the report itself.]

Throughout the whole of this cruise the temperature of the *sea-bottom* was taken by the protected Miller-Casella Thermometers in nearly every sounding. As, for the reason already mentioned, no extreme depths were sounded, and as the general rate of the diminution of temperature on the margin of the North-Atlantic basin seemed to have been established by the serial soundings taken in the expedition of the preceding year, it was not thought necessary to repeat these; more especially as the variety of depths at which the *bottom*-temperature was ascertained gave adequate data for comparison with the results then correlated. It will be shown hereafter that this comparison leads to some very interesting conclusions, fully confirming the view advanced in the last report as to the slow northward movement of an upper stratum of warm water 700 or 800 fathoms in depth, and of the southward movement of the whole deeper stratum, bringing water of an almost icy coldness from the Arctic basin into the temperate and even the intertropical zone.

During the whole of this expedition the temperature of the *surface* of the sea was ascertained and recorded every two hours, both by day and by night; as were also the readings of the Dry and Wet-bulb Thermometers, which were placed in a small penthouse on deck, in which they were freely exposed to the surrounding air, but secluded from direct or reflected solar heat. The temperature of the *surface-water*, from the time of our leaving the British Channel in lat. 48° N. to our turning the corner of Cape St. Vincent in lat. 36° 50′ N., increased at a rate which bore a pretty regular proportion to the Southing. Thus, at the "chops of the Channel," it averaged 62° for five days; whilst, by the time we approached Cape St. Vincent, it had gradually risen to above 69°. After passing that point, however, we found both the *surface* and the *bottom*-temperatures to present certain variations, which, though not considerable in themselves, proved to be of great interest when taken in connection with the peculiar condition of the *embouchure* of the Strait of Gibraltar. These points, however, will be more fitly discussed hereafter; and we shall now only notice a sudden *rise* in surface-temperature of about 3° which showed itself as we turned the corner of Cape St. Vincent and entered the *north side* of the embouchure; and a sudden *fall* of nearly 6° (to 66°·4) which was encountered when we entered the mid-stream of the narrower part of the Strait as we proceeded towards Gibraltar.

In the course of the first portion of the cruise between Falmouth and Lisbon (beyond which point Mr. W. L. Carpenter was unable to proceed), thirty-six quantitative determinations were made by volumetric analysis, of the amount of chlorine in as many samples of Atlantic water, taken (1) from the surface, (2) from the bottom at various depths, and (3) from various intermediate depths. The greater part of these, as will be shown hereafter, indicated a very close conformity to a uniform standard of density, as indicated by a specific gravity of 1·0268, and a Chlorine proportion of 11·84 per 1000;* the chief departures being observable in the *lower* density of the *deepest* waters, and in the occasional *excess* of density in the surface-waters. The former is doubtless attributable to the fact that the *deepest* water is essentially *Polar*, and therefore derives its more dilute character from that source. The latter we are inclined to attribute to the influence of slight concentration by evaporation.

Second Cruise.—Leaving Gibraltar early in the morning of Monday, Aug. 15, we steamed out into the middle of the Strait, for the purpose of commencing our experiments on the Gibraltar current. The point selected by Capt. Calver (Chart of Strait of Gibraltar, Station 39) lay midway between Point Carnero, which forms the south-eastern boundary of Gibraltar Bay, and Jebel Musa or Apes Hill, which lies opposite to it, at a distance of only 8 geographical (9¼ statute) miles, on the African coast, the Strait being here nearly at its narrowest; and it was also that at which the greatest depth (510 fathoms) was indicated by the soundings marked on the Chart. With this depth our own sounding, which gave a bottom at 517 fathoms, agreed very closely; and having thus at once found the position most advantageous for our work, that position was precisely determined by angles taken by sextant from the ship between conspicuous objects on the shore. The *bottom*-temperature obtained in the first sounding was between 5° and 6° *higher* than that which had been met with at corresponding depths on the bed of the Atlantic about 100 miles to the westward; whilst the *surface*-temperature was *lower* by from 1°·3 to 2°, as will be seen by the following comparative statement:—

	Station.	Depth.	Surface temperature.	Bottom temperature.
			°	°
Strait of Gibraltar	39	517	70·0	55·5
Atlantic	31	477	71·3	50·5
Atlantic	32	651	71·5	50·0
Atlantic	33	554	72·0	49·7
Atlantic	34	414	71·7	50·0

This striking difference led us to take a set of *serial* soundings at intervals of 50 fathoms, and these gave a result, which, though it appeared anomalous at the time, was afterwards fully explained, and proved to be of unexpected import. The temperature fell, at 50 fathoms from the surface, to 56°; at 100

* The proportion here adopted,—the number of Grammes of Chlorine to 1000 Cubic Centimetres of water, is that employed by Prof. Forchhammer in his elaborate Memoir on the Composition of Sea Water (Phil. Trans. 1865).

fathoms it was 55°·7; at 150 it was 55°·5; and from that depth to the bottom, at 517 fathoms, there was *no further descent.* Now, it will be shown hereafter that the thermal condition, which here so much surprised us by its contrast with that of the Atlantic waters, is that universally met with in the Mediterranean, the temperature of which, whatever may be its surface-elevation, falls to within 1° Fahr. above or below 56° at a depth of 50 fathoms, to a degree lower at 100 fathoms, and then remains uniform down to the greatest depth (1,743 fathoms) at which we examined it. And it thus appears that whilst the *surface*-water in this part of the Strait is certainly derived from the Atlantic, the *deeper* water, partaking of the thermal condition which so remarkably characterises that of the Mediterranean basin, may be fairly regarded as belonging to the latter.

This inference is in harmony with another fact ascertained on the same occasion, viz., the great excess in salinity shown by water brought up from the depth of 250 fathoms over the water of the surface. Whilst the specific gravity of the latter was found to be 1·0271, that of the former was 1·0293; and whilst the proportion of chlorine in the latter was 20·034 per 1,000, it was 21·775 in the former. Now in these particulars the surface-water agreed well with what had been found to be the condition of the water of the Atlantic, whilst the water at 250 fathoms agreed equally well with what proved to be the condition of the water at the like depth in the adjacent part of the Mediterranean. We were not a little surprised, however, to find that the water taken from the *bottom* (517 fathoms) was of much *less* density, as indicated both by specific gravity and by chlorine percentage, than that of the *intermediate* stratum; its specific gravity being 1·0281, and its proportion of chlorine 21·465. This apparent anomaly (the existence of which was confirmed by observations made on our return voyage) pointed to the existence of an out-current in the *intermediate* stratum as the probable explanation of the overlaying of the lighter by the heavier water. The specific gravity of the *bottom*-stratum closely corresponded, as we subsequently found, with that of the bottom-water over the deepest part of the area of the western basin of the Mediterranean.

These data having been obtained by the examination of the several parts of the vertical column at one and the same point, and this point being in the centre nearly of the narrowest part of the Strait, and at the deepest part of the channel, we proceeded to test the *actual movement* of water on the surface and at different depths beneath it.

The rate of *surface*-movement was easily determined. The precise position of the ship having been ascertained in the manner already stated, a small flat basket, presenting no such elevation above the water as would cause it to be influenced in any considerable degree by a moderate wind,* was sent adrift, so as to be freely carried along by the current; it was allowed to float for a determinate time, throughout which it was followed by the ship, and when it was taken up at the expiration of that time, the place of the ship was again ascertained as before. The space between the two points being then determined trigonometrically, the rate of the flow per hour, and its precise direction, could be readily calculated. Thus on the morning of August 15th the float was followed by the ship for fifteen minutes, during which it was found to have moved 4,377 feet in the direction E. by S. ¾ S., or at the rate of 2·88 miles per hour.

For the determination of the *movement of the water at different depths below the surface*, a current-drag had been constructed by Capt. Calver on a plan suggested by his previous experience; which had led him to the conclusion that a submerged basket lined with sail-cloth, which of course fills itself with water, presented a better resisting surface than any vessel of wood or metal. Such a basket being made the basis (so to speak) of the apparatus, its resisting surface was augmented by fixing two pairs of arms at right angles to one another across its upper end, and stretching a piece of sail-cloth between each arm and the side of the basket, which device caused a uniform resisting surface to be presented to the current whatever the manner in which the sails might meet it. To the lower part of this "drag" a couple of sinkers, of 112lb. each, were attached; and the whole apparatus was supported by cords meeting in a ring above it, to which the suspending line was secured.

* It is obvious that the movement of the ship itself would be liable to be considerably affected by even a slight breeze, on account of the large surface of resistance presented by its transverse section (especially by its paddle-boxes) above the water. This would cause its drift to be *more* rapid than the current, if the direction of the wind should be *with* that of the current, and *less* rapid if the wind should be opposed to it.

This "current-drag" having been transferred to a boat, was lowered down by a couple of men placed in her, to the desired depth; and the boat was then left entirely free to move, being lightened by the return of the men into the ship. The motion of the boat would be the composite result of (1) the action of wind (if any) upon the tranverse section of the part of the boat above the water; (2) the action of the surface-current upon the transverse section of the immersed part of the boat; (3) the action of the upper current upon the suspending line; and (4) the action of the current in which the "drag" is suspended, upon the drag itself. Putting aside the *first* of these agencies, which will be of very little account if (as in the experiment now narrated) the boat be small and the breeze be light, it is obvious that the relative influence of the *second* and *third* to that of the *fourth* will depend upon the proportion between the surfaces presented by the boat, the line, and the "drag" respectively, and the strength of the current acting upon each. The surface given to the "drag" being larger than that of the boat and line taken together, the force acting on the "drag" will dominate, if it hang in an opposing current superior, equal, or even somewhat inferior in rate to that which acts on the boat and line, so that the boat would be carried along by the drag *against* the surface stream at a rate proportioned to the excess. If, again, the rate of the under-current should be greatly inferior to that of the surface, its action upon the "drag" might still be sufficient to neutralise that of the surface-current upon the boat and line, and the boat would then remain *stationary*, or nearly so. A still further reduction in the rate of the op-

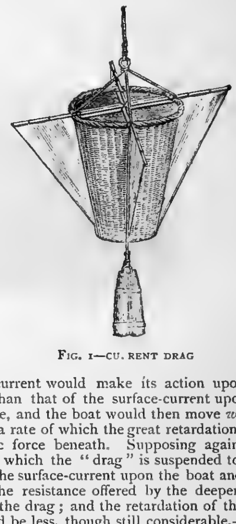

FIG. 1—CURRENT DRAG

posing under-current would make its action upon the "drag *less* powerful than that of the surface-current upon the boat and suspending-line, and the boat would then move *with* the surface-current but at a rate of which the great retardation would indicate an antagonistic force beneath. Supposing again, the water of the stratum in which the "drag" is suspended to be stationary, the action of the surface-current upon the boat and line would be opposed by the resistance offered by the deeper water to the movement of the drag; and the retardation of the movement of the boat would be less, though still considerable.—If, again, the stratum in which the "drag" is suspended should itself be moving in the direction of the surface-current, but at a reduced rate, there will still be a resistance to the movement of the "drag" at the more rapid rate of the surface-current; and this resistance will produce a proportional retardation in the motion of the boat. Finally, if the stratum in which the "drag" is suspended, with the intermediate stratum through which the suspending line passes, move at the same rate with the surface-current, the motion of the boat with the whole suspended apparatus will have the same rate as that of the simple float.

Putting these respective cases conversely, it may be affirmed (1) that if the boat, having the "current-drag" suspended from it, should move *with* the surface-current and *at the same rate*, the stratum in which the "drag" hangs may be presumed to have a motion nearly corresponding with that of the surface-current; (2) that if the rate of movement of the boat *with* the surface-current should be *retarded*, a diminution of the rate of the stratum in which the drag hangs to a degree *exceeding* the retardation of the movement of the boat, may be safely predicated; (3) that when this retardation is so considerable that the boat moves *very slowly* in the direction of the surface-current, it may be inferred that the stratum in which the drag is suspended is either stationary, or has a slow movement in the opposite direction; (4) that if the boat should remain *stationary*, a force must be acting on the "drag" which is equal, and in the *contrary direction*, to that of the upper current upon the boat and suspending line; so that the existence of a counter-current is indicated, having a rate as much *less* than that of the surface-current as the resisting surface presented by the "drag" is greater than that offered by the boat and upper part of the suspending line; (5) that if the boat should move in a direction *opposed* to that of the surface-current, a motion is indicated in the stratum in which the "drag" hangs, which will correspond in *direction* with that of the boat, and which will *exceed* it in *rate*, the effect of the "drag" upon the boat being partly neutralised by the antagonistic drift of the surface-current.

Now our first set of experiments with the "current-drag" gave the following results:—

(1.) The surface-movement being first tested in the manner already described, its rate was found to be 2·88 nautical miles per hour, and its direction E. by S. $\frac{3}{4}$ S. The wind was W. by N., with a force of 4.

(2.) The "drag" having been lowered down to a depth of 100 fathoms, the rate of movement of the boat from which it was suspended was reduced to 1·550 mile per hour, or *rather more than half* the surface-movement. Its direction was E. $\frac{1}{3}$ S. Taking into account the action of the wind and surface-current on the boat, it may be safely affirmed that at 100 fathoms the rate of the current was reduced to *less than one half.*

(3.) The drag having been lowered down to a depth of 250 fathoms, the boat remained nearly stationary, its *rate* of movement being reduced to 0·175 mile per hour, while its direction (S.E. $\frac{1}{2}$ E.) was slightly altered to the southward, though still easterly. From this we felt ourselves justified in inferring that the 250-fathoms' stratum had a movement in the *reverse direction*, acting on the current-drag with a force almost sufficient to neutralise the action of the upper stratum on the boat and suspending line. And this inference is strengthened by the extraordinary density of the water of this stratum, and is fully justified by the results of the experiments which we made on our return-voyage.

While these experiments were in progress, we had the pleasure of seeing the Channel Fleet, which was expected to meet the Mediterranean Fleet at Gibraltar, come in sight beyond Cape Tarifa; its approach having been indicated, long before even the tops of the masts of the vessels composing it showed themselves above the horizon, by the number of separate puffs of smoke which the experienced eye of our Captain enabled him to distinguish. As soon as all possibility of doubt was removed by the appearance of the masts, Capt. Calver communicated "Fleet in sight" by signals to the Admiral in Gibraltar Harbour; our position being such that *we* could be seen by him, though the Fleet could not. In due time, the massive hulls of the ironclads rose above the horizon, and whilst we continued at our work, all passed us in sailing order, at a distance of not more than a couple of miles, the ill-fated *Captain* being the chief object of interest. A few hours later, the *Monarch*, which had been detained for repair, but whose passage had been made in a shorter time by the free use of her steam-power, came in sight, and passed on in solitary grandeur to join the fleet, now united in Gibraltar Bay.

The whole of our first day having been consumed without our being able to work the "current-drag" in the deepest stratum, we anchored for the night near Point Carnero, with a view

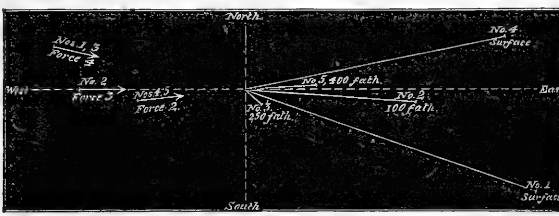

FIG. 2—Rate (per hour) and Direction of Movement of Surface-Float, and of Current-Drag at different Depths; with Force and Direction of Wind

to resuming our experiments on the following morning. We then ran out to a spot almost precisely identical with that which had been our starting-point on the previous day; and commenced as before, by testing the rate and direction of the surface-movement. Its rate proved rather slower, being 2·40 miles per hour, instead of 2·88; and its direction was E. by N., instead of E. by S. $\frac{3}{4}$ S. Both differences seemed to be accounted for by the difference in the force and direction of the wind; which, having been W. by N. with a force of 4 on the previous day, was now W. $\frac{1}{2}$ S. with a force of only 2. The "drag" was then lowered to a depth of 400 fathoms; but our expectation that it would there encounter a westerly (or outward) current sufficiently strong to carry the boat in that direction in spite of the antagonistic movement of the easterly (or inward) surface-current, was not verified on this occasion; for the boat slowly drifted in an E. $\frac{1}{3}$ N. direction, its rate being 0·650 mile per hour. Whether this result should be taken to indicate a stationary condition of the deep stratum, or a slight movement in either direction, can scarcely be affirmed with positiveness; but from the indication afforded by the specific gravity of the water taken up from this depth, it would seem probable that the general movement of this stratum was at this time rather *westerly*, or in conformity with that which we attributed to the intermediate stratum, though at a slower rate. It will be shown hereafter that a decisive proof of such a movement was obtained on a subsequent occasion.

Thinking it expedient to postpone the further prosecution of this inquiry until our return-voyage,—when we should be able to repeat our experiments, not only at this narrow end of the Strait where it enters the Mediterranean Basin, but also at that shallowest portion to the westward, where the Strait opens out into the Atlantic,—we put steam on before mid-day, and entered the basin of the Mediterranean, directing our course in the first instance to the spot (lat. 36° 0′ N., long. 4° 40′ W.) at which the sample of bottom-water had been obtained by Admiral Smyth, which, when analysed by Dr. Wollaston, was found to possess the extraordinary specific gravity of 11·288, and to yield a percentage of 17·3 of salt.* As we were within sight of both shores, and could distinguish several remarkable mountain-summits which were accurately laid down on our charts, the bearings of these enabled the situation of the ship to be determined with great precision; and Captain Calver undertook to place her within a mile of the point at which Admiral Smyth's observation had been taken. Having reached this, we took our first sounding in the Mediterranean, and awaited the result with no little interest. The depth proved to be 586 fathoms, or 84 fathoms less than that given by Admiral Smyth's sounding; but as the latter was not taken on the improved method now adopted, and as its correctness may have not improbably been affected by the strength of the easterly current which is here very perceptible, the discrepancy can scarcely be considered as of any real account as showing that the two points were otherwise than nearly coincident.† The

* Phil. Trans. for 1829, p. 29; and Admiral Smyth's "Mediterranean," pp. 128—130.

† Thus Admiral Smyth states ("Mediterranean," p. 159) the depth in mid-channel between Gibraltar and Ceuta to be 950 fathoms; whereas it is now known to be but little more than 500 fathoms. "A little farther to the eastward," he says, "there is no bottom with 1,000 fathoms of line up-and-down (*upwards of* 1,300 *payed out*);" whereas the greatest depth as far east as Malaga Bay is now known not to exceed 750 fathoms. These errors are noticed in no invidious spirit, but merely to prevent their perpetuation. Admiral Smyth doubtless made the very best use of the means at his disposal; but a far more satisfactory method has now entirely superseded that formerly adopted.

specimen of bottom-water brought up by our bottle was found to have a specific gravity of 1·0292, whilst that of the surface-water was 1·0270. The volumetric determination of the chlorine gave 21·419 per 1,000 for the bottom-water, as against 20·290 per 1,000 for the surface-water. A decided excess of salt is thus indicated in the bottom-water, as compared on the one hand with the surface-water of the same spot, and on the other, with the bottom-water of the Atlantic, which had been generally found to show a rather smaller proportion of chlorine than the surface-water. But this excess is extremely small in comparison with that indicated by Dr. Wollaston's analysis. For, assuming his factor of ·134 as representing, when multiplied by the excess of specific gravity above that of distilled water, the total per-centage of salt, that per-centage is only 3·91, instead of being 17·3, as stated by Dr. Wollaston.

This result accorded so closely with that obtained by Dr. Wollaston himself from the analysis of two other samples of bottom-water taken up by Admiral Smyth, the one in long. 1° E. from a depth of 400 fathoms, and the other in long. 4° 30′ E. from a depth of 450 fathoms, as well as with our own determinations of the specific gravities and chlorine per-centages of a great number of samples taken in different parts of the Western basin of the Mediterranean, that we cannot hesitate in regarding it as representing the *ordinary* condition of the bottom-water at this spot. And it seems to us far more probable that the sample furnished by Admiral Smyth to Dr. Wollaston had been concentrated by evaporation in a badly-stopped bottle in the three years during which it had remained in Admiral Smyth's possession, than that any extraordinary discharge of salt from a brine-spring at the bottom (a sort of *Deus ex machinâ* invoked by Admiral Smyth to account for the occurrence) should have given rise, in the spot at which his sounding was taken, to an exceptional condition of which no indication whatever was presented in our own.

The temperature-phenomena presented at this Station proved of singular interest. The *surface*-temperature, 74°·5, was higher than any that had been encountered on the Atlantic side of the Straits, even in a latitude half a degree farther south; and the observations which had been regularly taken every two hours showed that it had increased nearly *ten degrees* as we proceeded eastwards from Station 39, between 10 A.M. and 2 P.M. A part of this increase was doubtless due to the heating effect of the midday sun; but as the temperature of the air had not increased quite *six* degrees during the same time, and as it will be shown hereafter by a comparison of the diurnal averages of the surface temperature of the Mediterranean with those of the Atlantic, that the latter are at least four or five degrees higher than the former, it may be fairly assumed that at least half the increase was due to the passage from the colder Atlantic water of the mid-channel into the warmer water of the Mediterranean basin, the temperature of the latter being even here somewhat reduced by the inflow of the former.—The *bottom*-temperature was found to be here 55°; and this corresponded closely with that which we had met with in the Strait, while it was at least 5° higher than had been obtained at corresponding depths on the Atlantic side. Being desirous of determining the rate of its diminution, we took *serial* soundings at intervals of 10 fathoms down to 50, and then at 100 fathoms; with the following remarkable result:—

		diff. 0·1
586 ,, (bottom)	55·0	

Thus there was a fall of 9°·5 in the first 20 fathoms; of 5°·3 in the next 30 fathoms; of 4°·6 in the next 50 fathoms; whilst from 100 fathoms to the bottom at 586 fathoms there was no further descent.

Whilst we were prosecuting these inquiries, we found ourselves surrounded—the surface of the sea being extremely calm—by great numbers of the beautiful floating *Velellæ*, which are occasional visitors to our own coast, accompanied by the *Porpitæ*, which are more exclusively restricted to warmer seas. With these was a great abundance of a small species of *Firola*, about 0·4 inch in length, the extreme transparence of which enabled every part of its organisation to be readily studied microscopically, its nervous system being specially distinguishable. Of this very interesting *Heteropod*, a full description will be hereafter published by Dr. Carpenter.

The result obtained by our first temperature-sounding in the Mediterranean, was fully borne out by that of the temperature-soundings taken during three subsequent days; which show an extraordinary uniformity of *bottom*-temperature at depths from 162 to 845 fathoms *:—

Station. No.	Depth, in faths.	Surface-temp. °	Bottom-temp. °
41	730	74·5	55·0
42	790	74·0	54·0
43	162	74·7	55·0
44	455	70·0	55·0
45	207	72·7	54·7
46	493	73·5	55·5
47	845	69·5	54·7

It will be observed that the surface temperature varied between 69°·5 and 74°·5; and that whilst the highest temperatures were shown at Stations near the African coast, the lowest presented itself between Cape de Gat and Cartagena. Now the Gibraltar inflow is very sensibly felt at Cape de Gat, where the current usually runs at the rate of a mile an hour; and of the strength of this current we had unpleasant experience. For on the 19th of August, as we were crossing from Station 46 towards the Spanish coast, we encountered a strong N.E. breeze, which, meeting the current, worked up a considerable swell; this prevented us from taking even a temperature-sounding on that day, and gave our ship a peculiar twisting or screwing movement, from which we were glad to escape by the subsidence of the breeze during the following night. During this day the surface-temperature of the sea came down from the average of 72°·2 which it had maintained on the 18th, to 66°·9. Had the weather been calm, we might have attributed this reduction to the colder Gibraltar in current; but as the average temperature of the air also fell from 73°·8 to 69°·8, and as the strong N.E. breeze must have had a cooling effect upon the surface of the sea, we should have deemed it probable that the reduction of surface-temperature was due at least as much to the latter as to the former of these causes, had it not been that a set of serial soundings which we took at Station 47 showed that the reduction extended very far down, as will be apparent on comparing the following results with those previously given:—

	°Fahr.
Surface	69·5
10 fathoms	59·0
20 ,,	57·5
30 ,,	56·5
40 ,,	55·7
50 ,,	55·3
100 ,,	54·7
845 ,, (bottom)	54·7

It will be seen hereafter that the observations made on our return voyage gave more distinct evidence of the cooling influence of the Gibraltar in-current.

At most of these stations we explored the bottom by means of the dredge, with results much less profitable than we had anticipated. Except near the coast, on either side, where the ground was rocky and unequal, the bottom was found everywhere to consist of a tenacious mud, composed of a very fine yellowish sand mixed with a bluish clay—the former predominating in some spots, the latter in others. Large quantities of this mud were laboriously sifted, often without yielding anything save a few fragments of shells, or a small number of *Foraminifera*; and in no instance was it found to contain any considerable number of living animals of any description. Our disappointment at this unexpected paucity of life was not small; and it was destined, as will hereafter appear, to continue through the whole of our dredging exploration of the deeper portions of the Mediterranean basin. The operation of dredging in the shallower portions nearer shore was rendered difficult by the rocky nature of the bottom, on which the dredge continually "fouled;" and after the loss of two more dredges and a considerable quantity of rope, Capt. Calver came to the conclusion that the "tangles" only should be used where the inequality of the soundings indicated danger to the dredge. Now the "tangles," whilst gathering

* This uniformity, as we have since learned, had been previously observed by Captain Spratt, in his Soundings in the Eastern Basin of the Mediterranean; but owing it seems probable to the want of "protection" in his thermometers, he had set the uniform temperature too high, namely 59°. (See his "Travels and Researches in Crete," vol ii. Appendix II.)

Polyzoa, Echinoderms, Crustacea, and the smaller corals, sometimes even better than the dredge, pick up but few shells; and hence our collection of Mollusca is altogether a scanty one. Nevertheless, many of the types we did obtain were of considerable interest. Thus at Station 45, at a depth of 207 fathoms, we got *Turbo Romettensis*, Seguenza, MS. (Sicilian fossil); *Scalaria plicosa* (Sic. foss.); *Odostomia obliquata*, Ph.; *Philine*, two undescribed species; and an interesting coral (*Dendrophyllia corrugosa*).

SCIENTIFIC SERIALS

THE *Geological Magazine* for January (No. 79) commences with an article by Mr. A. H. Green, on a subject which has lately attracted much attention, namely, the "Geological Bearings of the recent Deep-Sea Soundings." Mr. R. Tate contributes an article on the Invertebrate Fossils of the Lias, which includes a useful table of the known Liassic genera, showing the number of species in each found in Britain and on the Continent, with observations on the distribution of the genera, and descriptions of some new species. Mr. J. Clifton Ward has a paper on the Development of Land, illustrated by references to the geological history of Italy and England. In an article on the Transport of Wastdale Crag Blocks, Mr. Croll ascribes the distribution of those puzzling boulders to the action of land-ice, and adduces evidence in support of the opinion that the great ice-covering of Scotland overlapped the high grounds of the North of England. Mr. Hopkinson characterises a new genus of Graptolites, under the name of *Dicellograpsus*; it includes five species hitherto referred to *Didymograpsus*.

The February number of the same journal opens with a note on the Diamond-fields of South Africa, by Prof. T. Rupert Jones, in which the author endeavours to correlate the scattered and scanty information that we possess on the geology of that region. MM. Brady and Crosskey furnish lists of fossil Ostracoda obtained from the post-tertiary deposits of various localities in Canada and New England, with descriptions of six new species, illustrated by an excellent plate. From the Rev. Osmond Fisher, we have some interesting notes on phenomena connected with denudation observed in the so-called coprolite pits near Haslingfield in Cambridgeshire; and from Mr. Woodward a note on the new British Cystidean, *Placocystites Forbesianus* of De Koninck, which is identified, on the authority of Mr. Billings, with his *Ateleocystites Huxleyi*. The numbers also contain the usual notices, reviews, and smaller communications.

OF the *Württembergische Naturwissenschaftliche Jahreshefte* we have received the twenty-sixth volume, published in 1870, and including, besides the ordinary general notices of the Proceedings of the Natural History Society of Württemberg, some important papers in various departments of science.—Dr. Samuel Bartsch contributes a notice of the Rotifera observed by him in the neighbourhood of Tübingen, which he preludes with remarks on the anatomy and physiology of those animals. The species are not described, but the genera are characterised, and the author contributes valuable remarks on some of them. He establishes two new families: the Longisetæ, for the genera *Distemma*, *Rattulus*, *Furcularia*, and *Monocerca* of authors, and a new genus, *Monommata*, including *Notommata tigris* and *longiseta*; and the Loricata, for the reception of Ehrenberg's *Euchlanidota* and *Brachionæa*.—Prof. Fraas describes the progress of the geological investigation of Württemburg, and M. C. Deffner, the very curious structure of the Buchberg, an outlier of the Jura, near Bopfingen.—The most important geological paper is a notice of the fauna of Steinheim, relating principally to the remains of Miocene mammals and birds from that locality. This fauna includes, together with numerous well-known species some new forms of great interest, among which may be noticed especially, a species of *Colobus*, described by the author as *C. grandævus*; a new generic type allied to the badgers, and described as *Trochotherium cyamoides*; and species of *Chæropotamus* and *Tapirus*. The fauna is considered by the author to have its nearest existing representative in South-Eastern Asia and the great islands of the Indian Archipelago, and he regards the deposit as following in order of time, the "Langhian stage" of Carl Mayer, which includes the deposits of Weissenau, Oppenheim, Radoboj, and others in Germany; and of Arquato, Superga, Malta, and others in the South of Europe. This valuable memoir is illustrated with six plates.—Prof. C. W. Baur reports on recent geodetic surveys made in Württemberg, for the purpose of a European measurement of a degree.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, February 9.—"On the Problem of the In-and-Circumscribed Triangle," by A. Cayley, F.R.S.—The problem of the in-and-circumscribed triangle is a particular case of that of the in-and-circumscribed polygon; the last-mentioned problem may be thus stated—to find a polygon such that the angles are situate in and the sides touch a given curve or curves. And we may in the first instance inquire as to the number of such polygons. In the case where the curves containing the angles and touched by the sides respectively are all of them distinct curves, the number of polygons is obtained very easily and has a simple expression; it is equal to twice the product of the *orders* of the curves containing the several angles respectively into the product of the *classes* of the curves touched by the several sides respectively, or say it is equal to twice the product of the orders of the angle-curves into the product of the classes of the side-curves. But when several of the curves become one and the same curve, and in particular when the angles are all of them situate in and the sides all touch one and the same curve, it is a much more difficult problem to find the number of polygons. The solution of this problem when the polygon is a triangle, and for all the different relations of identity between the different curves, is the object of the present memoir, which is accordingly entitled "On the Problem of the In-and-Circumscribed Triangles;" the methods and principles are, however, applicable to the case of a polygon of any number of sides, the method chiefly made use of being that furnished by the theory of correspondence.

Anthropological Institute of Great Britain and Ireland, February 14.—Sir John Lubbock, Bart., M.P., F.R.S., President, in the chair. The President stated that this was the first meeting of the "Anthropological Institute of Great Britain and Ireland," since the union of the late Ethnological and Anthropological Societies under that name, and having vacated the chair in favour of Professor Huxley, proceeded to read a paper, "On the Development of Relationships." After some preliminary observations on the character of the family among the lower races of men, and the preponderance of the tribal tie, Sir John proceeded to discuss the conclusions drawn by Mr. Morgan from the valuable schedules of relationships collected by him and published by the Smithsonian Institution, especially with reference to his theory that the similarity between the Mohawk and Tamil systems indicated any Ethnological affinity between those races, a conclusion which Sir John was unable to accept. He then proceeded to show how in his opinion that similarity had arisen, and traced up the gradual development of correct ideas on the subject of relationships from the system of the Sandwich Islanders, which is the lowest on record, step by step to that of the Karens; showing that in each system there are points which can only be explained on the hypothesis of its development from a still ruder condition. He then compared these actually existing systems with those which would be produced by a retrogression of social customs, and showed that the systems of the lower races all indicate progress, and there are no instances of the existence of such a system as would arise in the case of degradation. He also laid stress on the fact that the social system is invariably in advance of the nomenclature of relationships, another evidence of progress as opposed to degradation. He showed that even in some European nations we have traces of earlier lower condition, and that therefore in the systems of relationships we have an interesting proof of the social progress of man, and the gradual development of family ties.—Mr. Hodder M. Westropp exhibited a Worked Flint Implement, said to have been found in a barrow, Ashby Down, near Ventor, Isle of Wight.—The Chairman announced that the meetings of the Institute would, during the remainder of the Session, be held on Mondays, commencing on Monday, 6th March.

Chemical Society, February 16.—Prof. Williamson, F.R.S., President, in the chair. The following gentlemen were elected fellows:—W. D. Herman, W. W Houlder, G. Lockyer, jun., W. J. Lockyer, J. E. Mayer, R. Meldola, M. M. P. Muir, W. J. Reynolds, W. Smith, T. E. Thorpe. The following papers were read:—"On the production of wood spirit," by E. T. Chapman. The author began by remarking that the difficulties of obtaining correct information regarding this production are very great. The manufacturers are too jealous to disclose their "secrets." The woods chiefly employed in wood distilling are oak, beech, birch, thorn, crab or apple, hazel, alder, and ash. Great preference is given to holly and yew, whilst poplar, elm, and the whole of the coniferous order are avoided. The ovens or retorts are of various forms, and either of cast or of wrought iron, protected outside by brickwork against the dire effects of the fire. The condensers of iron and copper are constructed so as to permit the ready passage of very large volumes of gas, and to admit frequent cleaning. The temperature at which the distillation is conducted influences the amount of the products; as a rule, greater heat yields more of the so-called naphtha, and a lower temperature more acetic acid. The liquid products of distillation which form two layers, are differently treated according to the object the manufacturer has in view. After having given a lengthy description of the various products obtained in wood distilling, the author went on to say that some easier and more exact methods of estimating the commercial values of the various products ought to be introduced.—"On the effects of pressure on the absorption of gases by charcoal," by John Hunter. Very numerous experiments lead to the observations—first, that the amount of absorption increases with the pressure to which the gas is exposed; and secondly, the same change of pressure produces about the same amount of increase in the quantity of each gas absorbed.—"On the solubility of the phosphates of bone-ash in water holding carbonic acid," by E. Warington.

CAMBRIDGE

Philosophical Society, February 13.—"On the Great Trigonometrical Survey of India," by Colonel J. T. Walker, R.E. The author carefully described the process of carrying out the survey and the instruments in use, pointing out the various difficulties which were experienced, and the mode in which they were overcome. He also gave an account of the earlier efforts in this field and pointed out the importance of careful survey, and the mode by which accuracy in geodelic investigations was secured. In conclusion he discussed the mathematical difficulties which presented themselves, and a theorem which had been found useful in the reduction of observations.

NORWICH

Naturalists' Society, January 3.—The chairman read a paper by Mr. W. M. Crowfoot, on Spontaneous Generation. After distinguishing between the *origin* of life and the *nature* of life, two very distinct subjects, which have at all times been more or less confounded with one another, Mr. Crowfoot proceeded to review briefly the history of the theories concerning the nature of life as propounded by Hippocrates, Paracelsus, &c.; he then gave a condensed history of the views concerning the origin of life, and of the experiments of Redi, Needham, Pasteur, Huxley, and Bastian, and a *résumé* of the discussion which has been recently carried on in the columns of NATURE and elsewhere; concluding with some practical remarks on the nature of epidemic diseases, and the important results which may arise from such discussions. The thanks of the meeting were voted to Mr. Crowfoot for his very interesting paper, which was followed by an animated discussion.

DUBLIN

Royal Geological Society, January 11.—Rev. Maxwell Close in the chair. Edward Hull, F.R.S., read a paper on the Geological Age of the Ballycastle Coalfield, and its relations to the Carboniferous rocks of the west of Scotland.—Mr. John Leech read a paper on the moving bog of Castlerea, Co. Roscommon.

February 8.—Dr. Reynolds in the chair. The annual report of council, and statement of accounts for the year 1870 were submitted, and the following were elected as officers and council for 1871:—President, the Earl of Enniskillen, F.R.S.; Vice-presidents, Colonel Meadows Taylor, J. Emerson Reynolds, Sir Robert Kane, F.R.S., Rev. H. Lloyd, Provost T.C.D., F.R.S.; Sir Richard Griffith, Bart., LL.D.; Treasurers, William Andrews, and Samuel Downing, LL.D.; Secretaries, Rev. S. Haughton, M.D., F.R.S., and Alexander Macalister, M.D.; Council, Alphonse Gages, B. B. Stoney, W. Frazer, George Dixon, Alexander Carte, M.D., W. H. S. Westropp, C. R. C. Tichborne, Rev. Maxwell Close, Francis M. Jennings, Ramsay H. Traquair, M.D., R. Callwell, John Barker, M.D., John Ball Greene, Edward Hull, F.R.S., William H. Baily.—Mr. J. Scott Moore read a paper on a moulded piece of quartz, and exhibited a remarkable specimen of dendritic markings in granite.—A paper was read from Mr. G. H. Kinahan on foliation.

PERTHSHIRE

Society of Natural Science, February 2.—Dr. Buchanan White, president, in the chair. Mr. C. Fleckstein read a paper upon the Zoology and Botany of the Ancients. The paper, which was of general interest, was confined almost entirely to a consideration of the knowledge of natural history possessed by those nations termed *par excellence* the *ancients*, viz., the Greeks and Romans, and related chiefly to the researches of Aristotle and Pliny. Mr. W. Herd read a paper upon the Lepidoptera of Moncrieffe Hill and its neighbourhood. It was illustrated by specimens of the insects mentioned, and contained the results of Mr. Herd's own observations of the habits of the less common species found in the district selected.

DIARY

THURSDAY, FEBRUARY 23.

ROYAL SOCIETY, at 8.30.—On the Mutual Relations of the Apex-Cardograph and the Radial Sphygmograph Trace: A. H. Garrod.—On the Thermo Electric Action of Metals and Liquid: G. Gore, F.R.S.

SOCIETY OF ANTIQUARIES, at 8.30.—On the Topography of Jerusalem, with special reference to the results obtained by the Palestine Fund Committee: Thomas Lewin, M.A., F.S.A. (Second paper.)

ROYAL INSTITUTION, at 3.—Davy's Discoveries: Dr. Odling.

THURSDAY, MARCH 2, 1871

THE SMALL-POX EPIDEMIC

THE present epidemic of Small-pox in London is the most destructive, we are told, that has occurred in London during the present century. This is a very painful disclosure, when it has been almost demonstrated that, of all contagious and epidemic diseases, it is the one over which man has the most control. It is a well-known fact that when persons have once had the small-pox they seldom or never take it again, and that the disease known as cow-pox is a modified form of small-pox, and that persons who have had this modified form of small-pox are as little liable to take this disease as those who have had the small-pox itself. This was the great discovery of Jenner, and the practice of vaccination has more than realised the hopes of its discoverer and his friends. Where vaccination has been carried out with energy, and communities by wise laws or individual action have seen that every child is duly vaccinated, there small-pox has not spread. It appears that where communities are all properly vaccinated, there, even if an isolated case of small-pox does occur, it has no pabulum to feed on, and it does not spread. It is only when the small-pox contagion is communicated to unvaccinated persons that the disease is set up, and has sufficient vitality to spread through a community. Forty-five millions of persons died in Europe from small-pox in the century preceding the introduction of vaccination, whilst it is calculated that it has not killed more than two millions of persons in Europe since the introduction of vaccination. In London, during the last century, one death in every fourteen was due to small-pox. Up to the present time in this century not more than one-fiftieth of the persons who have died in London have died of this disease Greater differences than even this have been observed in. some of the cities and towns of the Continent of Europe. At Trieste the deaths from small-pox have been seventy-five times less than before vaccination; in Moravia, twenty-one times less; in Silesia, twenty-nine times less; in Westphalia, twenty-five times less, and in Berlin, nineteen times less.* These instances might be indefinitely increased, but we are anxious to show to what extent this disease is really controllable.

Supposing even that it is not demonstrated that small-pox can be eradicated by vaccination alone, carefully collected statistics show that when small-pox is taken by the vaccinated, it is much less fatal than among the unvaccinated. In the epidemic now prevailing in the metropolis, it is found that not more than six per cent. of persons who have been vaccinated die of small-pox, whilst about thirty-six per cent. of those who have not been vaccinated die. This is the proportion of deaths observed at the Small-pox Hospital from 1836 to 1851, so that it will be observed that the small-pox has neither lost nor increased in malignity.

There is a question which we ought to allude to here, and that is, Does vaccination lose its protective power? The best observers are of opinion that when vaccination has been properly performed, and the system brought thoroughly under the influence of the cow-pox, a person has no more liability to take the small-pox than if he had had the small-pox itself. But unfortunately, from various causes, vaccination is either improperly performed, or the disease is only imperfectly developed, and in such cases it is desirable that re-vaccination should be effected. It is not however, possible to say by looking at an arm, whether the operation has been properly performed, or the disease has perfectly developed. Under these circumstances it is no doubt desirable that every person should be re-vaccinated at least once in his life. The best time for the performance of this operation, where persons have been vaccinated in infancy, is between the twelfth and twentieth year. But in times of epidemic every person in the household should be re-vaccinated who has not been so before.

Thus much with regard to our knowledge of one means of averting this disease. That this means has not been adopted, arises partly from the ignorance of our population, partly from the perversity of our vestries and boards of guardians, and partly from the feebleness of our legislators.

The ignorance of our population of the means of preventing ordinary diseases is astounding, and if left to themselves with regard to vaccination, they will do nothing, from sheer ignorance of the nature of small-pox or the nature of its great antidote. Our coroners' courts bear testimony to this, where poor people have excused themselves for not having their children vaccinated, by not being aware of its value or of the measures to be adopted to get the operation performed. Surely this is one of the subjects to be embraced by the "relations of man to the universe," recommended by Professor Huxley in his programme of the education of children under the new School Board.

The perversity of vestries and boards of guardians has much to do with the present unvaccinated state of London. This epidemic has not come on London unanticipated The medical officers of health in many districts warned their vestries of the coming evil, but, unfortunately, from our wholly exceptional legislation in sanitary matters, the power of looking after small-pox and vaccination is given to the Poor Law Board. The vestries have therefore thrown on the guardians the burden of providing for an attack of small-pox; and in many instances little or nothing has been done, either in the way of looking up the unvaccinated, putting in force the vaccination laws, or treating the first cases of small-pox with those precautions which the fearful nature of the disease imperatively demands.

With a bundle of Acts of Parliament passed at different times with different objects, and giving authority variously to the Privy Council, the Poor Law Board, the Home Secretary, and other bodies, it is no wonder that our Government acts feebly in sanitary matters. There have been no vigorous attempts on the part of the Government or the Legislature to meet the present outburst of small-pox. If cows and sheep had been attacked, it is probable that something new would have been done. The old machinery has, it is true, been kept in motion. There is the Vaccination Act, which threatens every person with a fine who does not have

* Further facts of this kind are recorded in Dr. Ballard's Essay on Vaccination. 1868.

his child vaccinated, but this law is regularly set at defiance. Besides this, even if boards of guardians and vestries are disposed to carry it out, they have no means of finding out unvaccinated children. There is, it is true, the Registration Act, but that Act does not make registration compulsory, and in some districts of London it has been stated that twenty-five per cent. of the population are not registered. There is no machinery yet set on foot to enable the inspectors of vaccination to lay hold of these children. Then there is the emigration of families from one parish to another. There is no plan of action for discovering these unvaccinated children in these families. It is vain for one parish to look after its vaccination, if other parishes do not. This is an Imperial question, and ought not to be left to Boards of Guardians.

But what can we do at once, so as, if possible, to avert the further course of the epidemic? We can hardly hope, from past experience, that the epidemic will cease at present, if nothing further be done. The measures which a knowledge of the nature of the disease would suggest are as follows:

1. There should be a vigorous attempt made at once to secure the vaccination and re-vaccination of all persons who have not yet undergone these operations. It is of no use to wait till such persons seek this for themselves. They must be found out, and found out at once. At the rate at which inspectors are now finding out the unvaccinated, the epidemic will have spent its force, and little, if any, life will be saved. But if the Legislature would at once interfere, and insist on a house-to-house visitation with a body of men armed with vaccine virus, and ability and power to vaccinate, the whole of London might be visited, and every inhabitant inspected or vaccinated, in the course of the next month. These agents must be medical men or medical students, who should be paid so much a day for their trouble. It is this question of paying that constantly hampers vestries and boards of guardians. They would rather see any number of people sick than pay to prevent their sickness. The Government must do it, and do it at once, or it will not be done at all. A few hundreds of pounds will do it, and it will save thousands that the small-pox would cost.

2. Vigorous efforts should be made to stamp out each case of small-pox where it occurs. Every case of the disease should be reported to the sanitary authority of the district, on pain of fine and imprisonment. The person affected should be either removed to a hospital or isolated. If the latter, the isolation should be complete. Satisfactory evidence of the isolation should be given to the medical officer of health, and unless he is satisfied with the means taken, some method of punishing the erring parties should be devised. Contagious diseases of all kinds may be thus arrested. It is the difficulty of discovering the first cases that makes the spread of contagious disease so rapid and extensive.

3. Disinfection should be insisted on. This subject requires more thought and attention than it has yet received. All possible means by which the poison can be conveyed from one person to another should be prevented. The poison of small-pox retains its vivaciousness or reproductive power more tenaciously, apparently, than any other animal poison. It can be conveyed in clothes, paper, thread, string, everything that it is possible to use in the sick room. The doctor may take it to his patients, the lawyer to his clients, or the clergyman to his congregation if he has been visiting the sick. The Levitical laws against leprosy would be hardly too severe to prevent the spread of small-pox. Rules of the most stringent kind ought to be laid down for the guidance of nurses and all persons entering the sick room. Above all, in every district where small-pox prevails, there should be a disinfecting apparatus. This should be an oven not heated by gas, but by a stove. The oven should be long enough to receive beds and all kinds of bed-clothes and wearing apparel. These things should be conveyed to the store in a covered van, which could at once be placed in the oven without opening it to remove its contents. Filthy rags and beds of straw and shavings should be burned in the stove. Such an apparatus is at present at work in the parish of St. Giles. It should be forthwith erected in every district in London. Even when the small-pox has killed its utmost, such ovens will be useful for a future war with the demon of contagion in some other form.

Will some philanthropic member of the House of Commons draw up a Bill embracing these suggestions, and get it passed into law as quickly as possible, so as to save the lives of some thousands of our population, and the faces and purses of many thousands more?

E. LANKESTER

GÜNTHER'S CATALOGUE OF FISHES

Catalogue of Fishes in the British Museum. By Albert Günther, M.A., M.D., LL.D., F.R.S., F.Z.S., &c. Eight volumes. (London, 1859-1870.)

THE recent issue of the eighth and last volume of Dr. Günther's Catalogue of Fishes brings to a completion one of the most laborious and important zoological works of the present epoch. For Dr. Günther's Catalogue is not a mere catalogue in the ordinary sense of the word, but rather a more or less complete history of all the known members of the class of fishes. Not merely the higher divisions of the class, but the genera and species are all fully characterised, and to each species is appended a list of the specimens of it contained in the British Museum. References to other species, either doubtful or not yet acquired by the national collection, are also added. When it is stated that our national collection of fishes now contains 29,275 specimens, some idea may be formed of the labour that has been involved in naming, arranging, cataloguing, and describing such a vast mass of materials. Each of these specimens has to be carefully examined, in many cases internally as well as externally, and to be compared with its brethren of the same and allied species, before it can be satisfactorily determined. Let our readers go through this process in the case of one fish, and they will be able to form some sort of idea of the amount of toil involved in repeating this experiment some thirty thousand times over. Dr. Günther has in fact expended about thirteen years of unremitting labour on this great work, and has had the good fortune to bring it to a felicitous conclusion. No general account of fishes has been published since Lacépede and Schneider's edition of Bloch about the beginning of the present century, as the celebrated "Histoire Naturelle des

Poissons" of Cuvier and Valenciennes, like too many other French publications, has never been finished.

When Dr. Günther commenced his labours in 1859, his work was apparently intended to be confined to the Acanthopterygian order of fishes, and the volumes were entitled accordingly. On the completion of this great order with the third volume in 1861, the scope and title of the publication were extended so as to embrace the whole class of fishes. The fourth volume, issued in 1862, was devoted to the Pharyngognathi and Anacanthini of Müller, whose system Dr. Günther has generally followed. Here, however, he has made a slight change in the nomenclature used by the great German Anatomist, considering that the structure of the fins is of more importance than that of the pharyngeal bones, and therefore changing Müller's name, "Pharyngognathi acanthopteri" into "Acanthopterygii pharyngognathi.' '

In the fifth volume of his work, issued in 1864, Dr. Günther commenced the order Physostomi, treating first of the Siluroids and allied forms, which were formerly associated with the Salmonidæ; in the sixth, published two years later, the Salmonidæ themselves were handled. This group, Dr. Günther informs us, both on its own account and from the large amount of literature involved in its investigation, offers such great difficulties to the ichthyologist, that "as much patience and time are required for the investigation of a single species of it as in the case of other fishes for that of a whole family." The ordinary method followed by naturalists in distinguishing and determining species is here utterly inadequate; and Dr. Günther does not hesitate to assert that "no one, however experienced in the study of other families of fishes, will be able to find his way through this labyrinth of variations without long preliminary study, and without a good collection for constant comparison. Sometimes forms are met with so peculiarly and so constantly characterised, that no ichthyologist who has seen them will deny them specific rank; but in numerous other cases one is much tempted to ask whether we have not to deal with a family which, being one of the most recent creation, is composed of forms not yet specifically differentiated."

Dr. Günther's preliminary remarks (vol. vii. p. 3), before he commences the discussion of the true *Salmones*, well merit perusal by any naturalist engaged on the differentiation of species. In the Salmonidæ, characters such as the proportion of one part of the body to another, and the number of fin-rays, which in other groups of fishes are generally employed for the separation of species, fail entirely, and another set of characters has to be relied upon. To add to the confusion, some of the species at least *interbreed*, and "it is probable, although at present not yet confirmed by direct observation, that such hybrids mix again with one of the parent species, thereby producing an offspring more or less similar to the pure breed." The difficulties thus added to the correct determination of the Salmonidæ, may be easily understood.

The seventh volume of Dr. Günther's work, published in 1868, continues the history of the order Physostomi, and is devoted mainly to the extensive families Cyprinidæ and Clupeidæ, and to smaller groups nearly allied to them. In the eighth and last volume, published last year, Dr. Günther concludes the Physostomi with the eels and their allies, and then treats of the Lophobranchii and Plectognathi, which form the two last orders of the Teleostian subclass of fishes. The small subclass *Dipnoi*, embracing only the two Lepidosirens, comes next, and to them is appended a short notice of the recent discovery of the new Australian Mud-fish, which Mr. Krefft has referred to the Agassizian genus *Ceratodus*.* Dr. Günther states his inability at that period to determine whether it "should be referred to the Dipnoans or to the Ganoids, or should form the type of a separate subclass." But it is well known that he has since received perfect examples of this wonderful fish, and has in preparation a memoir which will, no doubt, put at rest all questions upon its structure and its position in the natural series.

The Ganoids (of which, formerly multitudinous, subclass Dr. Günther only recognises *six* existing species) and the Chondropterygians, or Sharks and Rays, follow next in order, and the eighth volume concludes with the two undoubtedly lowest forms of the class of fishes—the Lampreys and the Lancelet, an *invertebrated* vertebrate.

The total number of specimens of fishes in the collection of the British Museum at the period of the close of this great work was, as we have already said, 29,275. These are referred by Dr. Günther to 5,177 species. Besides these, 1,666 other species are recognised as valid, of which the national collection has not yet obtained examples, and 1,682 more are referred to as doubtful. "Assuming, then," says Dr. Günther, "that about one half of the latter will ultimately be admitted into the system, and that since the publication of the volumes of this work, about 1000 species have been described elsewhere, we may put the total "number of fishes at present known as about 9000."

In the preface to the last volume, Dr. Günther, besides giving us a general *résumé* of the extent of the collection under his charge, enters very fully into several other questions which are well worthy of attention, particularly at the present moment, when the relations between Government and Science are undergoing investigation by a Royal Commission. Whilst expeditions, fitted out by Austria, Prussia, and Italy, are despatched round the globe, accompanied by a staff of naturalists, and bringing back large collections of fishes to the national museums, our navy, it appears, is almost inert on this subject. Except from the Magellan Straits Surveying Expedition, to which Dr. Cunningham was attached as naturalist, no contribution from our Admiralty, which has so many ships always afloat, has reached the ichthyological department of the British Museum of late years. Yet it cannot be doubted that a very few words of encouragement from my Lords of the Admiralty would induce some of the many naval officers whose time must hang heavy on their hands at foreign stations, to turn their attention to collecting the common objects of the element on which they pass their lives. We assume, of course, that the expense of attaching a competent naturalist to any foreign expedition would be so great that "*my Lords would not feel justified in incurring it!*" Yet even the economical government of the United States thinks differently, and "each exploring American expedition was and still is accompanied by collectors, employed solely for the benefit of public museums."

* See NATURE, vol. ii. p. 106.

We should also, did not space fail us, like to call special attention to Dr. Günther's remarks on the importance of the study of the class of pikes as regards the elucidation of some of the most perplexing problems of Biology. "No other class of vertebrates," says our author, "is of equal importance to the geologist and palæontologist: the materials for comparing the living with past creations being so numerous and so diversified that we cannot help thinking that the relation of the various epochs to one another will be solved in the fields of ichthyology. Although fishes are mostly hidden by the elements in which they live, so that the knife of the anatomist generally first reveals new facts connected with their life, we have sufficient evidence to show that the phenomena of life are more varied in their different groups than in any other of the higher vertebrata, and that their study will form a solid basis for the solution of those general biological questions which, perhaps rather prematurely, agitate the minds of many zoologists."

OUR BOOK SHELF

On the Relations between Chemical Change, Heat, and Force. By the Rev. H. Highton, M.A.

We should not have noticed this paper, though it has been sent to us for review, had it not been marked as "Reprinted from the *Quarterly Journal of Science.*" This is its sole claim on our attention.

To put the contents in their simplest form before the reader, we may at once say that the Rev. Mr. Highton is a Perpetual-motionist. Not, perhaps, consciously—rather the reverse—but he belongs *in fact* to that singular class, though he would probably deny the charge with indignation. A short extract or two will, however, be sufficient to prove it to the satisfaction of any one acquainted with modern physics. Take the following:—

"Does there not, then, exist a power in nature for force to multiply force—even in the same way as life is multiplied by life through successive generations, and one living being may in due time become a thousand without losing its own vital energy?"

"We cannot . . . . produce heat without at the same time producing virtually in some shape or other an equivalent of cold."

"Cannot skill, mere skill, produce a less or greater disturbance and restoration of equilibrium, and so more or less force?"

If these extracts, which are perhaps not the richest which a careful search may discover, be not sufficient for the reader's amusement, we refer him to the original work. If they be not sufficient to prove to him the justice of our remarks, we refer him at once to some good scientific text-book, for he will have amply proved his need of instruction.

It would be an insult to our instructed readers to suppose that the fallacies of this paper require to be exposed *seriatim* for their benefit. *Ex uno disce omnes.* One will be given presently. But before giving it, we must strongly protest against the way in which many of the early, and some even of the later, discoveries of Joule are ignored throughout, while the attempts made to verify them by inferior experimenters, are put forth as original researches. When, however, Joule *does* happen to be referred to, the description of his experiments is wonderful indeed. Here is an example:

"He (Joule) churned various liquids in a calorimeter, and measured the increase of temperature. But in this kind of motion, as, perhaps, in all cases of friction, there is a pulling exertion of force, as well as one of pushing. Behind the arms of the paddle-wheel in the churn the liquid is pulled, and is pushed before them."

Comment on this sort of thing would be thrown away. When men like Helmholtz, Rankine, and Thomson vouch for the accuracy of a proposition, the world may well be indifferent to the criticisms of a Heath or a Highton. The grand founders of a rapidly progressing science cannot turn aside from their labours to answer frivolous objections. And it is strange and sad, indeed, that such excellent journals as the *Philosophical Magazine*, the *Quarterly Journal of Science*, and the *Chemical News* should diminish the space at their disposal for facts, by affording facilities for the dissemination of palpable nonsense and error.

As regards Electro-dynamics, Mr. Highton follows in the track of several better-known men, and is thus to a certain extent relatively excusable for his blunders, though they are quite as grave as those he commits with reference to the general theory of Conservation of Energy. The subject is by no means a very easy one, and it would certainly be somewhat hard to explain in a thoroughly popular manner the causes of his error. His difficulties, however (so far as we have had patience to investigate them), are such as have been met and overcome long ago by Joule, Faraday, and Thomson. (See, especially, Thomson, *British Association Reports*, 1852.) They are due, in great part, to his having confined his attention to the *zinc* alone of a galvanic cell.

Our Feathered Companions. Conversations of a Father with his Children about Sea birds, Song birds, and other feathered tribes that live in or visit the British Isles, their habits, &c. By the Rev. Thomas Jackson, M.A. (London: S. W. Partridge and Co.)

Dogs and their Doings. By the Rev. F. O. Morris, B.A. (London: S. W. Partridge and Co.)

The first of the books of which we give the titles above, is one we cannot take up without pleasure, because of the memories that its numerous illustrations bring to those who are shut up amongst bricks and mortar, of some wild sea-shore, sweet and tender woodland, or moor with gorse and fern; all of which are the homes of birds who would rather be free from the companionship of man than seek it, and which we love all the more for their wild freedom. "Our Feathered Companions" is full of information about birds, telling many well-known things about their habits and lives, of which children will never tire as long as there are children. With regard to the children in this book, we wish our author had drawn them from nature; we do not often meet with little boys who quote Greek out of school, and should be sorry if little girls were always moralising about birds being useful to man; we cannot read the narrative without feeling that their lives must have some other purpose beyond this, and we are glad that our children should be reminded by some of the little poems in the book, that they should love birds for their beauty, and learn all they can about them, rather than kill them to gratify a selfish desire for possession. The pictures of sea-birds are almost all charming, and there are many more of our favourite birds which, with a few exceptions, are very good.

"Dogs and their Doings" appears to be rather a compilation of old stories of wonderfully wise and clever dogs than the result of fresh observation,—the most extraordinary is of one which could pronounce words, and of another which understood the use of money; there are others which show wonderful affection and faithful memory for years after death. The book will be intensely interesting to children who love animals, they will recognise the tricks and sagacity of some of their friends in the dogs described; for dogs who know Sunday, and show great evidence of memory and reasoning powers, are to be met with in almost every family where they are cherished and loved. Some of the numerous illustrations are by Harrison Weir, others after Landseer; they are very attractive, though few of them are new.

Both volumes are got up in that attractive style with which we are familiar from Mr. Partridge, and make very pretty books for presents to young people.

Class Book of Inorganic Chemistry. By D. Morris, B.A. (London: George Philip and Son, 1870.)

THIS text-book is specially designed for pupils preparing for the Oxford and Cambridge Middle-class examinations and for the matriculation examination of the University of London. How far it will answer its purpose will be seen best by the number of students who use it as their guide and succeed in passing such examinations. Written for a special purpose, it is exempt from the criticism to which a general text-book would be subject, and we shall therefore amply point out how the book fails, in our opinion, to accomplish its purpose.

Nothing is more important for a student than that the definitions he learns should be clear and precise; yet those in this work are almost uniformly bad. Absolute *weight*, for example, is defined as "the amount of weighable matter in a body," which might have been simplified by saying, "weight is weight." Again, *solution* is defined as the "perfect union of a solid with a fluid," thus making the hydration of caustic lime an example of solution, and excluding the solution of gases in liquids.

It would be unjust to the author to state which nomenclature he has adopted; he has shown his impartiality by adopting nearly every one proposed; "potass," "potash," "potassium hydrate," and "caustic potash," are used indifferently; "sulphate of potassium" and "dipotassic sulphate" are used as synonyms for the substance having the formula $HKSO_4$. But the most objectionable feature in the book is a certain looseness of expression, leading to positive errors, which is certain to perplex the student. Examples of this abound; we need only quote a few. The solution of ammonia in water, we are told, "has all the properties of the gas;" again, "strontia forms with water a hydrate which has all the properties of baryta water," and "lime-water has all the properties of solutions of potash and soda."

Several statements occur in the book which are so absurd that they can only be traced to careless revision; but although they will scarcely mislead the merest tyro in the study of chemistry, they are none the less objectionable. We thought it very absurd to read that "combustion in air and in oxygen is exactly the same thing," and we thought it more absurd to read that "ammonium and sodium are distinguished by the smell of ammonia on the addition of caustic potash," but we only arrived at the climax of absurdity when we read that "nitrogen increases the volume of the atmosphere; and in this way provision is made for winds and other things useful for man's well being." Surely after this the text-books will cease to tell us that nitrogen is a very inactive substance.

It is only fair to say that the latter portions of the book are tolerably free from such errors as we have noticed; and the chapters on the heavier metals are the best in the book. Questions selected from the examination papers of Oxford, Cambridge, and London Universities, and the Science and Art Department, are given in several places, and the book concludes with tables for the analysis of simple salts. It is doubtful if a work of the size and scope of the one before us was at all needed, when there are so many excellent small manuals; but if such a one is really required, it must be much more carefully compiled and edited before it can be either useful or instructive.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Measurement of Mass and Force

"W. M. W." seems to regard units of mass and force as things which are to be talked and philosophised about, rather than to be actually used for the measurement of concrete qualities. It is true that the force of gravity on a standard pound at a specified locality is a definite unit of force; but instead of specifying a locality to which reference is by common consent to be made (and without which consent we shall have as many different units as there are localities), he says, "The assumption of a hypothetical force of gravity not dependent on latitude seems to stand on the same footing as the employment of a mean solar day."

The average length of the apparent solar day is the same at all places on the earth, and is called a mean solar day. I am curious to see "W. M. W.'s" definition of a hypothetical force of gravity not dependent on latitude. It appears to me to be such stuff as dreams are made of.

As your readers are probably nearly tired of this discussion, I propose to conclude it on my side by the following summary of the whole question:—

Mass and *quantity of matter* are generally identified, and were identified by Newton in the opening paragraph of the Principia; but I am disposed to agree with "W. M. W." so far as to allow that the comparison of quantity of dissimilar kinds of matter is to a certain extent conventional, though there is, perhaps, no other convention which has so strong a basis of reason. If it is the case that all kinds of matter consist of one elementary material differently arranged, this convention must of necessity be no longer a convention, but a simple statement of fact, and portions of dissimilar matter which have equal masses, whether as measured by the inertia test or the gravitation test, consist of equal quantities of the elementary material. The rigorous agreement which is known to hold between these two tests, as applied to the comparison of different kinds of matter, may even be quoted as an argument for the existence of such a common material.

Whatever we may think of this convention or assumption (call it which we will), the phrase *a pound of matter* is legitimate and involves no assumption. A pound of sugar is a pound of matter, and a pound of lead is a pound of matter, independent of all hypothesis.

All authorities are agreed that, in treating kinetical problems, it is expedient to express masses and forces in such units as to satisfy the relation.

$$\text{Force} = \text{Mass} \times \text{Acceleration},$$

which, for a body, falling freely in vacuo, becomes

$$\text{Gravitating force} = \text{Mass} \times g.$$

Now comes the point of divergence, the main question being this: shall we (I.) measure force by reference to a standard of mass, or shall we (II.) measure mass by reference to a certain (or uncertain) standard of force. I showed in my last letter (p. 228) that the pound is practically, in going from place to place, a standard of mass, not of force, and that masses in different localities can be more directly compared than forces. It is surely reasonable to measure force by reference to a universally accessible standard of mass, rather than to measure mass by reference to a standard of force which, on the earth generally, is difficult of identification. I therefore uphold the following system:—

I. Take a pound of matter as the unit of mass; from which it follows that the gravitating force of a pound of matter has the numerical value g, and the unit of force is $\frac{1}{g}$ of the force with which a pound of matter gravitates.

This system was first proposed by Gauss, for the comparison of magnetic forces in different parts of the earth. It is the system which has been always taught by Sir William Thomson, and is adopted in Thomson and Tait's Natural Philosophy, Tait and Steele's Dynamics (except the first edition), the Reports of the Brit. Assoc. Committee on Electrical Standards (see especially the Report for 1863), Balfour Stewart's Elementary Physics, and the later editions of Atkinson's Ganot.

If we adopt the other alternative, we are driven to choose between certain subordinate alternatives, of which, with "W. M. W.'s" help, I may enumerate three.

II. (1.) Localise your pound of force by specifying the standard locality of reference where the imperial pound gravitates with unit force. For this unit to be generally adopted, there must be general agreement as to the locality of reference, or what amounts nearly to the same thing, general agreement as to a definite reference-value of g. If we make this 32·2, the unit of force, at a locality where g has any other value, will be $\frac{32.2}{g}$ of the local gravitating force of the imperial pound, and the unit of mass will be the mass of 32·2 imperial pounds, so that the units will be a definite multiple of those employed in I.

This system is sound because (though in a roundabout way) it acknowledges the pound as a universal standard of mass, which is everywhere to be denoted by the same number, while it denotes the gravitating forces of pounds in different latitudes by different numbers.

If we take as unit of force the gravitating force of half an ounce at a place where g is 32, we obtain a clumsy definition of the Gaussian unit of force, and our unit of mass becomes the pound.

(2.) File or load your pounds so as to make a pound at the pole gravitate with the same force as another and larger pound at the equator. This is the only way of making the pound a direct *standard of force* to the inhabitants of the world generally. The unit of mass will then be g times the mass of one of these filed or loaded pounds, and will everywhere represent the same mass.

(3.) Let every man adopt the local gravitating force of an imperial pound at the place where he happens to be, as his unit of force, and the mass of g imperial pounds as his unit of mass. This system gives a rough and ready unit of force, which is frequently adopted for rough purposes by all physicists; but experimental results stated in terms of it must be accompanied by a statement of the local value of g, to make them comparable with those obtained at other places. In dealing with masses in cases where forces are merely subsidiary, as in buying and selling goods, no one would recommend the adoption of the unit of mass which this system gives. In cases where forces and masses have to be considered in conjunction, this system has no advantage over I. in point of simplicity, and has the disadvantage of requiring us to express both forces and masses in terms of changeable units which tend to confusion of ideas. It is altogether inapplicable to astronomy, and is not even competent to express the mass of the earth; for it would make the mass of a cubic foot of matter at the earth's centre many millions of times greater than the mass of a cubic foot of gold or platinum at the earth's surface.

Writers who, without special explanation, express forces in pounds or grammes, and say that the mass of a body is numerically equal to its weight divided by g, must be classed as adopting this system; for though such expressions are ambiguous in themselves, this is the sense in which they will usually be received and applied. It is indeed the system which was almost universally taught until the publication of Thomson and Tait's Natural Philosophy.

I am not quite clear as to the particular system which "W. M. W." elects to adopt. He began (p. 145) by siding with Deschanel, who seems to adopt II. (3). In answer to my first letter (p. 167), he stated (p. 187) that "if a true pound, as determined at London, were carried to the North Pole, it would weigh more than a pound." If this be not an adoption of II. (2), it amounts to saying that at the North Pole a pound does not weigh a pound. In the second sentence of his last letter he adopts II. (1) without, however, distinctly committing himself to a definite locality of reference; and as long as this point is left open, every man will make the locality where he happens to be the locality of reference, so that II. (1) in this indefinite form degenerates into II. (3). In the same letter he says, "As a philosophical theory, I am perfectly ready to admit that the standard pound is most appropriately considered as a standard of mass, but the employment of this standard in a text-book for the use of beginners seems calculated to lead to confusion." It rather appears to me that the refusal to accept this real standard of mass leads usually to a confused mixture of the systems II. (1), II. (2), II. (3); and I have shown in this letter that II. (1), which is the best of the three, does, in fact, make the pound a standard of mass.

I would earnestly commend to all teachers of dynamics the practice of Sir W. Thomson in strictly abstaining from the use of the word *weight* in all definitions and specifications relating to mass and force, as its ambiguous use does more than anything else to confuse these subjects. The weight of a body may and most frequently does mean its mass stated in pounds, or it may mean the force with which it gravitates. In the one sense its weight is the same whatever place it is carried to; in the other sense it varies from place to place.

I would also recommend for imitation Sir W. Thomson's practice of discarding the term *accelerating force*, which has been used to denote what ought to be called *force per unit of mass* or *intensity of force*, as distinguished from amount of force. Forces should always be expressed in terms of comparable units. As long as the learned recognise two non-comparable measures of force, they can hardly blame the unlearned for recognising a third and confounding force with energy.

The phrase *absolute force* (of a centre) is for the same reason objectionable. *Strength* of a centre is a better designation, and magneticians already speak in this sense of the strength of a magnetic pole. It would be a great advantage to have a short and handy name for some unit of force properly so called, and I venture to propose that the unit of force defined in I. be called a *kinit*. It may be formally defined as *that force which, acting on an avoirdupois pound of matter for a second, generates a velocity of a foot per second*. If we substitute gramme for pound, and metre for foot, we obtain a different unit which must be called by a different name, and of which 138¼ make one kinit. This numerical relation remains true, even if one of the forces compared be at the earth and the other at the moon. If any etymologist objects to making a word derived from Greek end in *it*, he may adopt the convenient fiction that it is an abbreviation of *kinetic unit*.

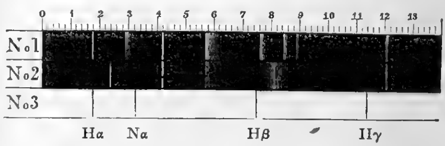
The Spectrum of the Aurora

IN the *Philosophical Magazine* for February there is a paper by F. Zöllner, on the Aurora Spectrum, in which he points out that, since the light of the aurora is as faint as that of the faintest vacuum-tube capable of being spectroscopically examined, while the mass of incandescent gas is almost infinitely greater, its temperature must be exceedingly low comparatively. He therefore supposes "that the spectrum of the aurora borealis does not correspond with any known spectrum of the atmospheric gases, only because, though a spectrum of our atmosphere, it is one of another order, and one which we cannot yet produce artificially."

I do not know if any other observer has noted the apparent coincidence in position of several of the auroral bands with those of a spectrum which I have occasionally obtained from air at low pressure, and with a feeble discharge. It is sometimes exhibited with great brilliancy by ordinary "lumière" tubes, and is, I believe, in part at least, the spectrum described by Wüllner (*Phil. Mag.*, June 1869), as a new spectrum of oxygen. I have certainly obtained it very vividly in pure electrolysed oxygen, with a feeble discharge; but some perplexing observations make me rather doubtful of its origin.

In the annexed sketch No. 1 represents the spectrum above



mentioned, No. 2 that of the aurora, while No. 3 gives the lines of H and Nα for comparison.

I first noticed the coincidence of the yellowish-green line at 41 with the principal line of the aurora in Jan. 1870, and since that time have frequently repeated the observation; once with a spectroscope with a 60° bisulphide prism, and magnifying power of about six times. With this instrument the lines of both spectra appeared nebulous, but perfectly coincident. When the light from the vacuum tube is strong, this band appears shaded off gradually on the most refrangible side, but when it is no brighter than the aurora this is not noticeable.

The faint lines shown in the sketch were never bright enough to be compared with the same accuracy as the bright line, but repeated observations convince me that the positions given cannot be far wrong. Their relative brightness is very variable.

The red line, which was so brilliant in the auroral displays of last October, is very rarely visible, and does not coincide with any line which I have observed. The first red line of the tube spectrum is Hα, due to a trace of residual moisture.

I think it best to publish these imperfect results without more delay, in the hope that they may be corrected or confirmed by other observers, as I am unable at present to continue the research. HENRY R. PROCTER

Royal College of Chemistry, Feb. 7

Resemblances of Plants *inter se*

MR. BENNETT, in his very interesting review of Mr. Mivart's "Genesis of Species" (NATURE, No. 66), refers to the close resemblance of an African Euphorbia and a South American Cactus" as an instance of "imitation," and to "the extraordinary resemblance of certain Conifers to flowerless plants" as "opposed to the theory of Natural Selection."

Neither example seems to be well chosen. In every case of supposed "mimicry" or "imitation," the question first arises, whether the resemblance between different organisms be or be not referable to similar conditions of life. Nobody will think a dolphin "imitates" a fish, nor does a climbing Tamus "imitate" a Humulus. These are cases of similar adaptations, but wholly unconnected with anything like mimicry in its true sense. An aquatic mode of life, or climbing habits, will necessitate certain peculiarities of structure, and the influence of an epidermis precluding evaporation will be the same in a Euphorbia as in a Cactus. The consecutive similarities of detail may without straining be referred to Mr. Darwin's "Correlations of Development."

There is still less cause for wonder in the resemblance of Conifers to flowerless plants, since it has been long ago shown by Hofmeister ("Vergleichende Untersuchungen," 1851, cf. Sachs, Lehrbuch der Botanik, 1868, pp. 310 and 384) that there is a close affinity between Lycopodiaceæ and Conifers, in spite of the chief boundary line of our system running between them. The resemblances of these respective orders therefore are scarcely more "extraordinary" than the resemblance of a Juncus to a grass, nor can I comprehend their bearing against the theory of Natural Selection.

Mr. Bennett deals rather strongly with botanists in denying to them, with rare exceptions, "a philosophic spirit." I cannot think this severe criticism to be applicable to the labours of Du Bary, Hofmeister, Sachs, Nägeli, Schwendener, Pringsheim, and other contemporaries of ours (confining myself to my own country), labours alike distinguished by comprehensiveness of generalisation and accuracy of detail.

Did Mr. Bentham really come over to "the evolutionists" "only within the last twelve months"? I should consider that he expressed his full assent to the ideas of Mr. Darwin already in his addresses of 1868 and 1869. D. W.

Frankfort-on-the-Main, Feb. 21

The Genesis of Species

IF this note should meet the eye of the writer on Darwinism in the *North British Review* for June 1867, I should feel greatly obliged if he would explain the following passage, quoted by Mr. Mivart in p. 57 of his "Genesis of Species":—"The advantage is utterly outbalanced by numerical inferiority. A million creatures are born; ten thousand survive to produce offspring. One of the million has twice as good a chance as any other of surviving; but the chances are fifty to one against the gifted individual being one of the hundred survivors."

Is it an assumption or the statement of a fact that "one of the million has twice as good a chance as any other of surviving?" and how are "the hundred survivors" arrived at?

STUDENS

Fertilisation of the Hazel

IN NATURE for April 7, 1870 (vol. i. p. 583), Mr. Marcus Hartog stated, as the result of his observations, that the male catkins and female flowers of the hazel are not simultaneously developed on the same twig, and that therefore a kind of quasi-cross-fertilisation necessarily takes place. Although convinced at the time that my observation did not tally with Mr. Hartog's, it was then too late in the season to submit my impression to a practical test. During the past week I have closely observed the hazel bushes in flower, and have found on every bush which has come under my notice, the female and male flowers in a perfect state of development on the same ultimate twigs, in close proximity to one another, the stigmas being frequently loaded with pollen-grains, apparently from the neighbouring catkin; at all events there appears no provision of nature specially to promote fertilisation from other bushes. We see in fact here a confirmation of the general law suggested in my paper in the first number of NATURE, on "The Fertilisation of Winter Flowering Plants," that when plants flower in the depth of winter, and at a time when no or few insects are about, self-fertilisation is the rule rather than the exception, or in the case of unisexual flowers, as near an approach to self-fertilisation as is possible under the circumstances. ALFRED W. BENNETT

Sanitary Tests

DR. LANKESTER recently pointed out in NATURE that the existence and spread of fever were mainly owing to popular ignorance and the neglect of physiological laws. Since the article referred to was written, a greater plague has followed the fever then prevailing; and we are now told that Ireland is much better off than England—vaccination being there almost universal.

This state of things seems to me but a symptom of a more deeply-rooted evil, viz., the general neglect of physiological and sanitary science among the *higher* orders as well as the lower.

In how many large schools are the laws affecting the human body and the relation of man's frame to the destructive and constructive elements which surround us systematically taught? Are there any?

We talk of the gross ignorance and filthy habits of the poor; but both their ignorance and their filthiness are often a part of the very conditions of their existence. Have *we* been faithful stewards in this great matter?

Allow me to draw attention to the fact that, though Government has greatly facilitated and cheapened the acquisition of other branches of science, hygiene seems entirely omitted from the programme. But knowledge must descend from the higher to the lower levels. Ought not the heads of all public schools to undergo a compulsory examination in this subject? I could adduce instances where the greatest mischief has resulted from ignorance in such high quarters.

Aigburth, Liverpool, Feb. 25 SAMUEL BARBER

Morell's Geometry

IN my ignorance of the fact that there are two Morells of very different calibres in the literary world, I find, to my great regret, that I have done serious injustice to the "widely-known" writer "on philosophy and grammar" and scholarly Mr. J. *D.* Morell, by attributing to him the authorship of the work on the "Essentials of Geometry," whose appearance I was compelled to notice so unfavourably in last week's NATURE. Pray give immediate publicity to this confession of error on the part of

March 1 THE REVIEWER

Algaroba

AT p. 313 of NATURE (February 16) is a paragraph on the use of the Algaroba in the province of Catamarca, Argentine Republic, in which it appears to me the writer has confounded two or more plants. Algaroba is a name applied to *Ceratonia siliqua*, to several species of *Prosopis* in South America, and to *Hymenæa Courbaril* in Panama. In Brazil the last-named plant in called Jatai, from which, I presume, the writer of the paragragh in question has obtained his "*Hymenæa Courbaril-Jetaiba.*" The sweet fleshy pods of *Prosopis dulcis*, a tree widely spread over Southern and Central America, are used for feeding cattle, and several other species are employed for a like purpose in different parts of the tropics; it is therefore more than probable that *P. dulcis* is meant instead of *Hymenæa Courbaril.* Moreover, the pods of this latter are very thick and woody, and would not be easily "pounded in a wooden mortar;" and the tree cannot be well described as growing "to a height of forty feet, with wide-spread branches, and a rather slender stem," when we know that it frequently attains a hundred feet in height, and sixty feet in circumference. JOHN R. JACKSON

Kew, Feb. 25

The Exeter Museum

THE paragraph in NATURE of the 23rd ult., respecting the Royal Albert Museum at Exeter, has excited my curiosity. Will you be so good as to mention an instance or two in proof that the museum "has done much towards attracting attention to the value of scientific knowledge in the West of England?"

It is difficult for a stranger to see how the case of the Plympton Grammar School can be ascribed to its influence.

Aurora Australis

[Extract from a letter received from Captain H. P. Wright, Ship *Gasfarth*]

Madras, Dec. 5.

I ENCLOSE you an account of the Aurora Australis as we saw it in the South, and I might also state that Mr. Pogson (Madras Observatory) says that the magnetic disturbance in these two days, 14th and 25th October, was so great that his instruments would not register the amount.

(Signed) H. P. WRIGHT

"October 24, 1870.—New moon at 6 P.M., lat. 42° S., long. 39° E.; at 7.30, as the twilight began to fade in the sky, we observed a bright rosy light at first resembling the reflection from a very red fire in the southern heavens. It extended from W. to E., and was visible from 8° to 50° high, being brightest at about 35° or 40°. Bright stars of the first and second magnitude shone through it. This cloud of crimson light had nearly all faded away by 9 P.M., first in the south-western direction, and so on gradually to the south-eastward. It may have been blown along by the wind, which was N.W. by W., but I did not think so. Other light clouds were passing; the sky below was its usual colour, and the stars shining very low down. As soon as this had passed away, there came a yellowish white, or milky white, light in the southern sky, and, as it were, taking the place of the crimson light. I should guess it to be about equal to $\frac{1}{3}$ of the moon s light, and showing a little bank of clouds of a dark-grey colour some 4° or 5° above the horizon underneath. This continued until 10.40 P.M., when it suddenly assumed a grander appearance. There was one long line of the brightest crimson some 8° or 9° broad, reaching up from south towards north, and some 70° high, fading into the normal colour of sky; this rose up a little to the west of the Southern Cross, on from this to the eastward was a great cloud or clouds of this bright crimson light, the bright star Canopus &c. showing through with a deep yellow light, and, passing over all, cumulus clouds carried somewhat quickly by the brisk breeze then blowing. To give, perhaps, a better estimate of the yellowish-white light, we could as long as it lasted only see the stars in the Southern Cross indistinctly. By midnight, or a little after, it all passed away, and we had lightning to the S.W. in the middle watch. The following night was very rainy, but the strong crimson and white light could still be discerned."

Aurora by Daylight

IN NATURE of Dec. 15, a correspondent asks the question, "Can Aurora be seen in daylight?" I answer, yes, beyond a doubt. In the autumn of last year (I cannot give the date nearer than that it was early in Ooctober) my eye was attracted by an unusual motion, in what at the first glance appeared to be a light fleecy cloud, but was in reality a broad ribbon of Aurora of a yellowish white colour, which changed its form and position with the peculiar streaming motion of the Aurora, sometimes almost fading entirely and again recovering its comparative distinctness.

It was about four o'clock in the afternoon when my attention was drawn to it, and I watched until late in the evening, and saw it as the dusk came on, supported by fainter streamers of light, which stole out as the darkness increased, and almost imperceptibly grew into one of those magnificent auroral displays so frequently seen here.

The Aurora, as I first saw it, was about N.W. by N., and I should say 30° above the horizon, and the sky was beautifully clear and free from clouds.

Will any of your correspondents inform me if the intensity of auroral light, as proved by its visibility in daylight, teaches us anything more than is at present known of the Aurora? And I should be much obliged to anyone who will inform me if the spectrum of lightning has ever been obtained, and if so, how it compares with the spectrum of the Aurora.

Matapediac, Province of Quebec, Feb. 4

Tigers at Bay

IN NATURE for Feb. 2, p. 275, a doubt is expressed as to whether a tiger when in danger will ever take to a tree. An anecdote related in vol. 2, p. 112 of De Beauvoir's "Voyage Round the World," seems to settle the question:—"Attacked and conquered by the buffalo, the tiger bounded some thirty feet into the air into a cocoa-nut tree. Some twenty natives were in an elevated position amongst the branches of this tree; in one and the same moment they let themselves fall like ripe fruit from a tree that is shaken." G. E. D.

Furzewell House, Torquay

Dr. Donkin's Natural History of the Diatomaceæ

THE reviewer of the above-named work (see NATURE, vol. iii., p. 210) describes the plates as inferior to those in the Synopsis. With this opinion I fancy many will differ; as correct representations of the species described, they are far in advance of those in the Synopsis, for example, compare the figure of *Navicula tumens* in the latter work with *Navicula rostrata* in Dr. Donkin's; with the exception of the outline, the figure in the Synopsis does not resemble that species, and is inferior to Ehrenberg's in the Microgeologie. Also compare *N. Hebes*, *N. palpebralis*, *N. subsalina*, *N. latiuscula*, *N. alpina*, with the corresponding forms in the Synopsis, and I think the superior fidelity of Dr. Donkin's illustrations will be conceded.

Many of the forms in the Synopsis must have been drawn from memory, they are so glaringly inaccurate, *e.g.*, *Amphipleura pellucida* is represented with marginal punctæ, *Nitzschia bilobata* with indistinct distant striæ. The marginal dots on *A. pellucida* existed only in the delineator's imagination; and, as every student of the Diatomaceæ knows, *N. bilobata* has close but distinct striæ.

I agree with "W." that the synonymy might have been more extended. It is, however, next to impossible to identify from figures or descriptions the forms intended by the early observers.

The desirability of giving habitats in full is questionable; three or four localities are sufficient, as with very few exceptions the same species would be found (the localities being similar) in any part of the United Kingdom.

In conclusion, I would remark that the following species are not Ehrenberg's, as stated by "W.," but Gregory's:—*Navicula Smithii* var. *fusca*; *N. Smithii* var. *suborbicularis*; *N. Smithii* var. *nitescens*, and *N. latissima*.

I know the works of Ehrenberg, Kutzing, Rabenhorst, Grunow, and Greville, but who is Cleeve? K.

PROPOSED OBSERVATIONS OF VENUS

THE following circular has just been issued by the Observing Astronomical Society:—

The committee of the society have decided to undertake a series of systematic observations of the planet Venus, during one complete revolution, for the purpose of obtaining results that shall lead to our becoming better acquainted with the markings which are visible on her surface, and a correct knowledge of their form and permanency.

In common with other observers it has been to them a matter of regret that although this beautiful object approaches nearer to us than does any other member of the solar system (our satellite excepted), yet that our knowledge of its superficial condition should be far less than of those planets less favourably situate. In most astronomical works the information concerning Venus is very meagre, whilst the drawings of her appearance exhibit, in the majority of cases, merely a blank crescent.

Yet, in turning to the ancient observations made of this planet, the committee have been struck by the large number recorded, many exhibiting well-defined markings, and when they considered the numerous observations of the same character made of late years, including several important ones from members of the society, it seemed evident that observation of this planet was not so difficult as is generally represented. It was seen further that if a proper discussion and analysis of all recorded observations were made, the result might be a large addition to our knowledge of the planet's surface.

The Committee, therefore, in inaugurating this important movement, divide the work to be done into three branches:—

1. The formation of a sub-committee of astronomical observers (including non-members of the society) for the purpose of continually observing Venus during one complete synodical revolution.

2. The collection of all ancient observations and drawings of the planet.

3. The collection of as much modern data as possible from existing observations, and from public and private records.

At the conclusion of the observations of the sub-committee, the results obtained, together with the ancient and modern observations collected, will be placed in the hands of a competent astronomer for complete analysis and discussion, when the results obtained will be published.

Those observers who are willing to join the "Venus Observation Sub-Committee" are requested to send their names and addresses to the hon. secretary of the Society, Ashley Road, Bristol, before March 10, stating the aperture and power of the instrument they intend to employ.

The observations will commence on March 20, previous to which a circular, containing full instructions, will be issued to every observer who has expressed his willingness to assist in the project.

PROFESSOR DE NOTARIS AND HIS NEW WORK ON MOSSES

IN the year 1838 Professor De Notaris, of the Universities of Turin and Genoa, published a Syllabus Muscorum, which he now calls *Un lavoro giovanile* (a juvenile work). Still it is a very useful manual for the young Italian bryologist, for whom it was first written, and to whom it gives not only the exact characters of each plant, but also their localities and the synonymy. From that time, year after year, he went on increasing and improving his work, till he had gathered together sufficient materials for a new work. It was not, however, till last year that he succeeded in persuading the bountiful municipality of Genoa to take his MS. in hand and publish it, which they effectually did at their own cost some months ago. The simple title of De Notaris' work* was mentioned by one English scientific periodical; but, except Dr. Braithwaite, the well-known contributor of the "Recent Additions to our Moss Flora," and Mr. C. J. Smith, who recently published a "Moss Flora of Sussex," accompanied by a clear and really instructive paper on the structure and reproduction of mosses,† I have hardly heard of any other English bryologist taking account of the newly edited *Atti della Università di Genoa*, the first of which, in large quarto, is entirely taken up by Professor De Notaris' standard work.

This painstaking and well-digested composition represents, as it were, the *résumé*, or, we might say, the quintessence of the long and seldom interrupted labours of the veteran bryologist, who, far from rejecting or disregarding the improvements that bryology has recently made, is quite willing to adopt them wherever he finds them of practical value, but not when, instead of the promised gold, they only give glittering or useless tinsel.

* "Epilogo della Briologia Italiana."

† "I have seen," writes Mr. Smith, "your friend's *Epilogo*, and am much struck with it. What a fine work, and brought out at the cost of the Municipality! When will such things occur in England?"

"I really find myself"—thus he writes in his preliminary comments—"in a sort of quandary (*specie di peritanza*) whenever I have to produce any ulterior, though obvious, re-adjustment, which might probably be attributed to some deplorable mania of upsetting and overthrowing the monumental edifice of the European bryology, or even to an ungracious instinct (*parmaloso istinto*) of seizing upon and appropriating the works of others. For, after all, we must acknowledge that the *Bryologia Europæa* (of Schimpfer) is the bible of every student of mosses."

Whilst admitting that any very small and apparently insignificant character may at times be useful to establish a natural group, De Notaris believes that such differential characters occasionally assumed, to complete the diagnosis of some genus or species, cannot be taken as absolute and invariable, and therefore he prefers to stick to the old Linnean canon: *Quæ in uno genere ad genus stabiliendum valent, minime idem in alio genere præstant.*

Thus pointing out the different forms of cells in the epicarp of *Bryum cæspitosum* and *B. erythrocarpum*, and seeing that it is not in the power of anyone to examine all the capsular membranes of each individual plant of these two species, he says: "We must not wonder if now and then an exception to the ruling character of the cells is to be found," observing, at the same time, that a pretty good character for distinguishing certain natural groups might also be found in the specific conditions of the *endochrome*. Another striking remark on this subject he makes, where he says that "the epithet *pachydermic*, applied to the cellule of the epicarps, might easily be a source of error, owing to either a stronger or weaker cohesion of the chromoplasm, in which case the cellules might well be pachydermic, and flocculently membranaceous at the same time."

He further observes upon the variable characters of the inflorescence that "*Mnium medium* is found both monœcious and polygamous, as well as *Bryum torquens* and *Bryum pendulum*. *Catoscopium* is not seldom to be found monœcious as well as diœcious. Even that form, he says, which I have distinguished under the name of *Bryum bimoideum*, may turn out at some time to be merely a diœcious form of *B. bimum*."

The *peristome*, in his view, is but an exudation or, as it were, a hypertrophy in the evolution of the capsule, not an indispensable means for the ripening of the sporules. Hence the reason why he considers it, morphologically speaking, as an apparatus of secondary importance. Thus there are specimens of *Hypnum stellatum*, which bear their ordinary normal capsules, whilst there are others whose capsules are like those of the apothecia, with imperfect and nearly Leskeaseous peristoms.

Other important reflections are to be found in the same "Comments," such as the one relating to the *perichætial* leaves, which serve to distinguish a *Limnobium* from a *Hypnum* better than any other distinction taken from the habit of the stem or the arrangement of the leaves; and the other on the topographical distribution of mosses in Italy, where the great variegation of the "Bryological mantle" mainly depends upon the various constitution, elevation, or undulation of the soil; the heights and the valleys, naked, or well timbered and green with copse and grove, variously contributing to their infinitely varied diversifications.

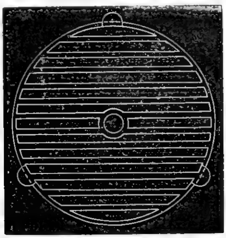
Among the vagrant species of all regions he points out particularly the *Bryum alpinum*, which, "from the uppermost boundaries of the Alpine zone, spreads itself down to the very brackish pastures that scarcely raise themselves above the sea level in the islets of the Strait of Bonifacio." Again, that gem of mosses *Schistostega osmundacea* (Bridel's *Catoptridium smaragdinum*) which has been till late a *desideratum* in the Italian flora, De Notaris informs us he found himself whilst, in 1865, he was crossing the Morgan on his way to Mont Rosa.

J. GAGLIARDI

A CONSTANT FORM OF DANIELL'S BATTERY*

GRAHAM'S discovery of the extreme slowness with which one liquid diffuses into another, and Fick's mathematical theory of diffusion, cannot fail to suggest that diffusion alone, without intervention of a porous cell or membrane, might be advantageously used for keeping the two liquids of a Daniell's battery separate. Hitherto, however, no galvanic element without some form of porous cell, membrane, or other porous solid for separator, has been found satisfactory in practice.

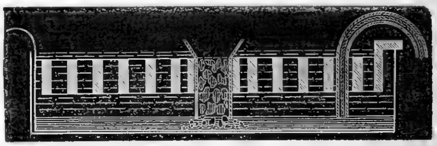
The first idea of dispensing with a porous cell, and keeping the two liquids separate by gravity, is due to Mr. C. F. Varley, who proposed to put the copper-plate in the bottom of a jar; resting on it a saturated solution of sulphate of copper; resting on this a less dense solution of sulphate of zinc; and immersed in the sulphate of zinc, the metal zinc-plate fixed near the top of the jar. But he tells me that batteries on this plan, called "gravity batteries," were carefully tried in the late Electric and International Telegraph Company's establishments, and found wanting in economy. The waste of zinc and of sulphate of copper was found to be more in them than in the ordinary porous-cell batteries. Daniell's batteries without porous cells have also been tried in France, and found unsatisfactory on account of the too free access of sulphate of copper to the zinc, which they permit. Still, Graham's and Fick's measurements leave no room to doubt but that the access of sulphate of copper to the zinc would be much less rapid if by true diffusion alone, than it cannot but be in any form of porous-cell battery with vertical plates of copper and zinc opposed to one another,



GROUND PLAN OF NEW BATTERY

as are the ordinary telegraphic Daniell's batteries which Mr. Varley finds superior to his own "gravity battery." The comparative failure of the latter, therefore, must have arisen from mixing by currents of the liquids. All that seems necessary, therefore, to make the gravity battery much superior instead of somewhat inferior to the porous-cell battery, is to secure that the lower part of the liquid shall always remain denser than the upper part. In seeking how to realise this condition, it first occurred to me to take advantage of the fact that saturated solution of sulphate of zinc is much denser than saturated solution of sulphate of copper. It seems† that, at 15° temperature, saturated aqueous solution of sulphate of copper is of 1·186 sp. gr., and contains in every 100 parts of water 33·1 parts of the crystalline salt; and that at 15° the saturated solution of sulphate of zinc is of sp. gr. 1·44, and contains in every 100 parts of water 140·5 parts of sulphate of zinc, both results being from Michel and Krafft's experiments.‡ Hence I made an element with the zinc below; next it saturated solution of sulphate of zinc, gradually diminishing to half strength through a few centimetres upwards; saturated sulphate of copper resting on this; and the copper-plate fixed above in the sulphate of copper solution. In the beginning, and for some time after, it is clear that the sulphate of copper can have no access to the zinc otherwise than by true diffusion. I have found this anticipation thoroughly realised in trials continued for several weeks; but the ultimate fate of such a battery is that the sulphate of zinc must penetrate through the whole liquid, and then it will be impossible to keep sulphate of copper separate in the upper part, because saturated solution of sulphate of zinc certainly becomes denser on the introduction of sulphate of copper to it. To escape this chaotic termination, I have introduced a siphon of glass with a piece of cotton wick along its length inside it, so placed as to draw off liquor very gradually from a level somewhat nearer the copper than the zinc; and a glass funnel, also provided with a core of cotton wick, by which water semisaturated with sulphate of zinc may be continually introduced at a somewhat lower level. A galvanic element thus arranged will undoubtedly continue remarkably constant for many months; but it has one defect, which prevents me from expecting permanence for years. The zinc being below, must sooner or later, according to the less or greater vertical dimensions of the cell, become covered with precipitated copper from the sulphate of copper which finds its way (however slowly) to the zinc. On the other hand, if the zinc be above, the greater part of the deposited copper falls off incoherently from the zinc through the liquid to the copper below, where it does no mischief, provided always that the zinc be not amalgamated,—a most important condition for permanent batteries, pointed out to me many years ago by Mr. Varley. Placing the zinc above has also the great practical advantage, that, even when after a very long time it becomes so much coated with metallic copper as to seriously injure the electrical effect, it may be removed, cleaned, and replaced, without otherwise disturbing the cell; whereas if the zinc be below, it cannot be cleaned without emptying the cell and mixing the solutions, which will entail a renewal of fresh separate solutions in setting up the cell again. I have therefore planned the following form of element, which cannot but last until the zinc is eaten away so much as to fall to pieces, and which must, I think, as long as it lasts, have a very satisfactory degree of constancy.

The cell is of glass, in order that the condition of the solutions and metals which it contains may be easily seen at any time. It is simply a cylindrical or rectangular jar with a flat bottom. It need not be more than ten centimetres deep; but it



SECTION

may be much deeper, with advantage in respect to permanence and ease of management, when very small internal resistance is not desired. A disc of thin sheet copper is laid at its bottom. A properly shaped mass of zinc is supported in the upper part of the jar. A glass tube (which for brevity will be called the charging-tube) of a centimetre or more internal diameter, ending in a wide saucer or funnel above, passes through the centre of the zinc, and is supported so as to rest with its lower open end about a centimetre above the copper. A glass siphon with cotton-wick core is placed so as to draw liquid gradually from a level about a centimetre and a half above the copper. The jar is then filled with semisaturated sulphate of zinc solution. A copper wire or stout ribbon of copper coated with india-rubber or gutta percha passes vertically down through the liquid to the copper plate below, to which it is riveted or soldered to secure metallic communication. Another suitable electrode is kept in metallic communication with the zinc above. To put the cell in action, fragments of sulphate of copper, small enough to fall down through the charging tube, are placed in the funnel above. In the course of a very short time the whole liquid below the lower end of the charging tube becomes saturated with sulphate of copper, and the cell is ready for use. It may be kept always ready by occasionally (once a week for instance) pouring in enough of fresh water, or of water quarter saturated with sulphate of zinc at the top of the cell, to replace the liquid drawn off by the syphon from near the bottom. A cover may be advantageously added above, to prevent evaporation. When the cell is much used, so that zinc enough is dissolved, the liquid added above may be pure water; or if large internal resistance is not objected to, the liquid added may be pure water, whether the cell has been much used or not; but after an interval, during which the battery has not been much in use, the liquid added ought to be quarter saturated, or even stronger solution of sulphate of zinc, when it is desired to keep down the internal resistance. It is probable that one or more specific gravity beads kept constantly floating between top and bottom of the heterogeneous fluid will be found a useful adjunct, to guide in judging whether to fill up with pure water or with sulphate of zinc solu-

* From the Proceedings of the Royal Society.

† Storer's Dictionary of Solubilities of Chemical Substances. Cambridge, Massachusetts: Sever and Francis, 1864.

tion. They may be kept in a place convenient for observation by caging them in a vertical glass tube perforated sufficiently to secure equal density in the horizontal layers of liquid to be tested by the floaters.

An extemporised cell on this plan was exhibited to the Royal Society, and its resistance (measured as an illustration of Mance's method, described in the first of his two previous communications) was found to be ·29 of an Ohm (that is to say, 290,000,000 centimetres per second). The copper and zinc plates of this cell, being circular, were about thirty centimetres in diameter, and the distance between them was about 7·5 centimetres. A Grove's cell, of such dimensions that forty in series would give an excellent electric light, was also measured for resistance, and found to be ·19 of an Ohm. Its intensity was found to be 1·8 times that of the new cell, which is the usual ratio of Grove's to Daniell's. Hence seventy-two of the new cells would have the intensity of forty of Grove's. But the resistance of the seventy-two in series would be 209 Ohms, as against 76 Ohms of the forty Grove's; hence, to get as powerful an electric light, threefold surface, or else diminished resistance by diminished distance of the plates, would be required. How much the resistance may be diminished by diminishing the distance rather than increasing the surface, it is impossible to deduce from experiments hitherto made.

Two or three cells, such as the one shown to the Royal Society, will be amply sufficient to drive a large ordinary turret-clock without a weight; and the expense of maintaining them will be very small in comparison with that of winding the clock. The prime cost of the heavy wheel-work will be avoided by the introduction of a comparatively inexpensive electro-magnetic engine. For electric bells, and all telegraphic testing and signalling on shore, the new form of battery will probably be found easier of management, less expensive, and more trustworthy, than any of the forms of battery hitherto used. For use at sea, it is probable that the sawdust Daniell's first introduced on board the *Agamemnon* in 1858, and ever since that time very much used both at sea and on shore, will still be found the most convenient form; but the new form is certainly better for all ordinary shore used.

The accompanying drawing represents a design suitable for the electric light, or other purposes, for which an interior resistance not exceeding $\frac{2}{10}$ of an Ohm is desired. The zinc is in the form of a grating, to prevent the lodgment of bubbles of hydrogen gas, which I find constantly, but very slowly, gathering upon the zincs of the cells I have tried, although the solutions used have no free acid, unless such as may come from the ordinary commercial sulphate of copper and commercial sulphate of zinc crystals which were used.

The principle which I have adopted for keeping the sulphate of copper from the zinc is to allow it no access to the zinc except by true diffusion. This principle would be violated if the whole mass of the liquid contiguous to the zinc is moved toward the zinc. Such a motion actually takes place in the second form of element (that which is represented in the drawing, and which is undoubtedly the better form of the two) every time the crystals of sulphate of copper are dropped into the charging-tube. As the crystals dissolve, the liquid again sinks, but not through the whole range through which it rose when the crystals were immersed. It sinks further as the sulphate of copper is electrically precipitated on the copper plate below in course of working the battery. Neglecting the volume of the metallic copper, we may say, with little error, that the whole residual rise is that corresponding to the volume of water of crystallisation of the crystals which have been introduced and used. It becomes, therefore, a question whether it may not become a valuable economy to use anhydrous sulphate of copper instead of the crystals; but at present we are practically confined to the "blue vitriol" crystals of commerce, and therefore the quantity of water added at the top of the cell from time to time must be, on the whole, at least equal to the quantity of water of crystallisation introduced below by the crystals. Unless a cover is added to prevent evaporation, the quantity of water added above must exceed the water of crystallisation introduced below by at least enough to supply what has evaporated. There ought to be a further excess, because a downward movement of the liquid from the zinc to the level from which the syphon draws is very desirable to retard the diffusion of sulphate of copper upwards to the zinc. Lastly, this downward movement is also of great value to carry away the sulphate of zinc as it is generated in the use of the battery. The quantity of water added above ought to be regulated so as to keep the liquid in contact with the zinc, a little less than half saturated with sulphate of zinc, as it seems, from the observations of various experimenters that, the resistance of water semisaturated with sulphate of zinc is considerably less than that of a saturated solution. A still more serious inconvenience than a somewhat increased resistance has been pointed out to me by Mr. Varley as a consequence of allowing sulphate of zinc to accumulate in the battery. Sulphate of zinc crystallises over the lip of the jar, and forms pendants like icicles outside, which act as capillary siphons, and carry off liquid. Mr. Varley tells me that this curious phenomenon is not unfrequently observed in telegraph batteries, and sometimes goes so far as to empty a cell and throw it altogether out of action. Even without this extreme result, the crystallisation of zinc about the mouth of the jar is very inconvenient and deleterious. It is of course altogether avoided by the plan I now propose.

In conclusion, then, the siphon-extractor must be arranged to carry off all the water of crystallisation of the sulphate of copper decomposed in the use of the cell, and enough of water besides to carry away as much sulphate of zinc as is formed in the use of the battery. Probably the most convenient mode of working the system in practice will be to use a glass capillary siphon, drawing quickly enough to carry off in a few hours as much water as is poured in each time at the top; and to place, as shown in the drawing, the discharging end of the siphon, so as to limit the discharge to level somewhat above the upper level of the zinc grating. It will no doubt be found convenient in practice to add measured amounts of sulphate of copper by the charging-tube each time, and at the same time to pour in a measured amount of water, with or without a small quantity of sulphate of zinc in solution.

As 100 parts by weight of sulphate of copper crystals contain, as nearly as may be, 36 parts of water, it may probably answer very well to put in, for every kilogramme of sulphate of copper, half a kilogramme of water. Experience (with the aid of specific-gravity beads) will no doubt render it very easy, as a perfectly methodical action involving very little labour, to keep the battery in good and constant action, according to the circumstances of each case.

When, as in laboratory work, or in arrangements for lecture-illustrations, there may be long intervals of time during which the battery is not used, it will be convenient to cease adding sulphate of copper when there is no immediate prospect of action being required, and to cease pouring in water when little or no colour of sulphate of copper is seen in the solution below. The battery is then in a state in which it may be left untouched for months or years. All that will be necessary to set it in action again will be to fill it up with water to replace what has evaporated in the interval, and stir the liquid in the upper part of the jar slightly, until the upper specific gravity-bead is floated to near the top by sulphate of zinc, and then to place a measured amount of sulphate of copper in the funnel at the top of the charging-tube.

W. THOMSON

NOTES

AT the Anniversary Meeting of the Geological Society, held on the 17th ult., the Wollaston Gold Medal was presented to Prof. Ramsay in recognition of his many researches in practical and in theoretical geology; and the balance of the proceeds of the Wollaston Donation Fund was given to Mr. Robert Etheridge in aid of the publication of his great stratigraphical "Catalogue of British Fossils." A report of the interesting proceedings on the occasion will be found in another column. Mr. Prestwich was re-elected President of the Society for the ensuing year.

A STATUTE was promulgated last week in Convocation at Oxford enlarging the powers of the delegates of "unattached students," whom it is proposed to allow to admit students after examining them in one of the subjects already permitted (*i.e.*, Classics and Mathematics), "together with some other subject recognised in the schools of the University" (*e.g.*, Physical or Natural Science).

We are indebted to *Harper's Weekly* for some of the interesting notes on science in America, which we are able to furnish this week, in advance of their publication there. This magazine provides its readers with an important and interesting summary in each issue of the progress of science on that side of the Atlantic.

Dr. Willie Kühne, at present Professor of Physiology at Amsterdam, has been called to occupy the chair left vacant at Heidelberg by the removal of Helmholtz to Berlin.

It is with great pleasure that we hear from the Abbé Moigno that the publication of *Les Mondes* will have recommenced before this, on March 1. Though the Abbé has escaped uninjured from the bombardment, a portion of his fine library was destroyed by a Prussian shell. We are still without files of any of the Paris papers.

In reply to a question in the House of Commons on Friday night last, Mr. Ayrton said that considerable progress had been made in the preparation of the plans for the erection of the Natural History Museum at South Kensington, but until they had been completed it would be impossible for them to receive the sanction of the Government.

The lectures of the present year for the Royal College of Physicians will be delivered at the College, Pall Mall East, at five o'clock on each of the following Wednesdays and Fridays Gulstonian lectures—Dr. Gee, March 3, 8, 10, "On the Heat of the Body;" Croonian lectures—Dr. Parkes, March 15, 17, 22, "On some points connected with the Elimination of Nitrogen from the Human Body;" Lumleian lectures—Dr. West, March 24, 29, 31, "On some disorders of the Nervous System in Childhood."

The third course of Cantor Lectures for the Session of the Society of Arts will be delivered by Dr. T. S. Cobbold, F.R.S., and will treat of "Our Food-producing Ruminants, and on the Parasites which reside in them." The course will commence on Monday, the 17th of April, and will be continued on subsequent Monday evenings till completed. These lectures are open to members, who have also the privilege of admitting two friends to each lecture.

Mr. Andrew Murray will, during the following season, deliver a short course of lectures for the Royal Horticultural Society on Economic Entomology, especially in its relations to Horticulture and Forestry. Mr. Murray has been mainly instrumental in forming the Society's collection of Economic Entomology exhibited in the South Kensington Museum.

Florida has, this winter, its usual complement of scientific visitors, who are engaged in prosecuting investigations upon its natural history. Mr. E. J. Maynard, of Massachusetts, is exploring the ornithology of the keys and the southern portion of the State; Mr. N. H. Bishop, of New Jersey, and Mr. George A. Boardman, of Maine, are at work with a similar object about Jacksonville. Professor Wyman, of Cambridge, is also making use of the opportunities of his third or fourth visit to the State in the critical examination of the ancient mounds and shell heaps which abound everywhere.

Dr. Packard has lately announced the discovery, by Prof. Verrill, of a dipterous larva of the genus *Chironomus*, at a depth of 120 feet, in the vicinity of Eastport, Maine. He also describes a mite, or *Acarus*, as occurring at a similar depth. He has not yet ascertained whether, like other species of the genus, the latter lives, in any of its stages, in the gills of the lamellibranchiate mollusca.

A recent communication to the State Department from the United States consul at St. Helena, states the fact that the white ants, which have effected a lodgment in the island, are rapidly destroying everything upon it. No wood but teak, and sometimes not even that, escapes their fangs; and numbers of houses in Jamestown have been fairly gutted by them—doors, window-sashes, floors, and roofs, all being eaten up, leaving nothing but the bare walls.

The following is a list of the German learned men connected with the French Académie des Sciences, copied from the *Comptes Rendus*, although some of them have died since the investment of the city, but their names were not erased from the list for want of official notification:—Four Associates, MM. Ehrenberg, Liebig, Wöhler, Kummer: three mathematicians, Neumann, Weierstrass, Kronecker; one mechanician, Clausius; three astronomers, Hansen, Argelander, Peters; three physicists, Weber, Mayer, Kirchhoff; two chemists, Bunsen, Hofmann; three mineralogists, Naumann, Rose, Haidinger; four botanists, Mohl, Braun, Hofmeister, Pringsheim; one anatomist, Siebold; three surgeons, Virchow, Rokitansky, Sebert.

The special correspondent of the *Times* gives the following account of the effects of the bombardment on the Jardin des Plantes:—No fewer than eighty-three shells had fallen within this comparatively limited area. On the night of January 8 and 9 four shells fell into the glass houses and shattered the greater part of them to atoms. A heap of glass fragments lying hard by testified to the destruction, but the effect of the shells was actually to pulverise the glass, so that it fell almost like dust over the gardens. The consequence was that nearly the whole of this most rare and valuable collection was exposed to one of the coldest nights of the year, and whole families of plants were killed by the frost. Some of the plants suffered the most singular effects from the concussion; the fibres were stripped bare, and the bark peeled off in many instances. All the Orchids, all the Clusiaceæ, the Cyclantheæ, the Pandaneæ were completely destroyed, either by the shells themselves or by the effects of the cold. The large palm-house was destroyed, and the tender tropical contents were exposed to that bitterly cold night; yet, singularly enough, although they have suffered severely, not one has yet died. All through the whole of the fortnight during which these gardens were subjected to this rain of shells, MM. Decaisne, Chevreuil, and Milne-Edwards, remained at their posts, unable to rest, and have since, at their own expense, repaired the damage done, trusting that whatever form of government France may choose, it will not repudiate its debts of honour. M. Decaisne is making out a list of his losses, a large proportion of which might possibly be supplied from Kew, while owners of private collections might also be glad to testify their sympathy and interest in the cause of science by contributing whatever they may be able to spare as soon as the amount and nature of the loss is ascertained. The animals fared better than the plants—not only have none of them been eaten by the population of Paris, as the latter fondly suppose, but although several shells burst among them, they have escaped uninjured. Of course, when food was so scarce for human beings, the monkeys and their companions were put upon short allowance. This fact, coupled with the extreme rigour of the season, increased the rate of mortality among them, and one elephant died, but was not eaten. The two elephants and the camel that were eaten belonged to the Jardin d' Acclimatation, and had been removed in the early stage of the siege from their ordinary home in the Bois de Boulogne, for safety, to the Jardin des Plantes, where, however, it would appear, it was not to be found. The birds screamed and the animals cowered, as the shells came rushing overhead and bursting near them, as they do when some terrific storm frightens them; latterly they seemed to become used to it.

We have great pleasure in announcing that the Museum of Natural History at Strasburg has escaped the bombardment of the town. One shell entered one of the corridors and destroyed a small collection of chalk fossils, and a few fragments of a shell decapitated two or three birds. The concussion caused nearly all the glass in the cases to be broken. But the fine collections of mammals, of birds, and of fossils, the result of many years of labour of Prof. Schimper, are perfectly untouched. This has not been the case with some of the private collections in the town, and one, a collection of European Lepidoptera, belonging to the Taxidermist of the museum, was scattered into dust.

WE learn with great regret that the Société d' Acclimatation of Paris has thought it necessary to pass a resolution erasing from the list of its members all sovereigns and princes of German States engaged in the late war against France, "considérant que la manière dont le bombardement de Paris a été effectué par les armées allemandes constitue un acte contraire au droit des gens, ainsi qu'aux plus simples notions de l' humanité."

AMONG the experiences of the Mount Washington winter party may be mentioned an exposure to perhaps the greatest cold ever recorded in the annals of science. The temperature of 40° below zero was not in itself unusual; but to this was added a hurricane blowing at the rate of ninety miles an hour. The combination of such a wind with the temperature indicated would probably have been entirely unsupportable but for the means of protection enjoyed by the party in the dwelling which had been fitted up expressly for their accommodation.

PROF. J. YOUNG has recently brought the question of the education of the mining engineers before the Institution of Engineers for Scotland. His proposals for its amelioration are as follows:—"1. Great improvement in secondary schools, especially in teaching arithmetic, geometry, elements of natural philosophy. 2. The establishment in some large towns, such as Liverpool and Birmingham, of colleges on the Scottish model, or on that of Owens College—fairly well endowed—giving chiefly general scientific training, with a few special technical chairs. 3. The practical recognition of the value of scientific training by engineers who take pupils. (*a*) By giving free pupilships or valuable scholarships; (*b*) By admitting as pupils only those who have passed certain recognised examinations; (*c*) By co-operating with colleges as examiners; (*a*) By inserting in agreements with their pupils that during winter they shall attend certain classes; (*e*) By giving some privileges, in connection with engineering societies, to graduates."

WE regret to learn that the fine specimen of *Pandanus odoratissimus* in the Botanical Gardens at Glasnevin, near Dublin, has been completely destroyed by the attacks of a fungus, in all probability the same that has destroyed the Screw Pine in the Breslau Gardens, as referred to by Prof. Oliver in a late number of this journal. The Glasnevin plant was nearly fifty years old.

MESSRS. BELL AND DALDY will shortly publish "Outlines of Magnetism and Electricity for Public Schools and Science and Art Examinations," being notes of a course of lectures delivered at the Royal School of Naval Architecture, with an introduction on the First Principles of Physics, by W. F. Barrett.

WE learn from the *British Medical Journal* that Dr. Thorne Thorne, who has been very successfully engaged for several years as an occasional inspector under the Privy Council, and who more especially led to the exposure of the causes of the Terling epidemic, has been appointed to a permanent position under the Privy Council.

THE *British Medical Journal* states that the rumour that Dr. Liebreich, the distinguished ophthalmologist of Paris, was likely to be appointed ophthalmic surgeon and lecturer at St. Thomas's Hospital, is likely to be realised. The reputation of Dr. Liebreich is more than European, and his services to ophthalmoscopic science and practice are such that he may fairly claim to be considered as almost the founder of our present school of ophthalmoscopy. The services which he has rendered to science are cosmopolitan, and we feel assured that if, under the existing state of affairs in Paris, Dr. Liebreich elects to take up his residence in London, his services, reputation, and personal character will secure for him that welcome which the English profession has always been wont to extend to distinguished men of science of every nation, and which well becomes the members of a liberal profession in a country proud of its freedom and hospitality.

TWO natives of the Garrow Hills in Madras are to be trained as vaccinators to practise in their tribe, which suffers severely from small-pox. On the other hand the villages in Kunnool oppose the entrance of vaccinators by force, and hide their children in the jungle.

THE Siam papers report the fortunate news of the capture of an albino or white elephant. He had been brought to the capital in state, and will in due time succeed to the highest dignities of state, the chief white elephant ranking next the Queen, and the heir apparent coming next only to this elephant.

MR. W. KING, of the Indian Geological Survey, reports from Ballary, in Madras, that he doubts the reported discovery of coal in that district.

THE *Homeward Mail* states that the cold has been so intense at the Mullier in Scinde lately, that on January 24th icicles were found on the works connected with the viaduct in that place. It is hardly possible to believe this phenomenon were it not communicated by a reliable eye-witness.

A PAPER, read to the Academy of Sciences, Paris, during the siege, gives some very interesting information about the great cold experienced there, and its occurrence in former years. In the fifty years from 1816 to 1866, the average temperature of the month of December has been 3·54° Centigrade above zero, but December, 1870, gave an average of 1·07° C. *below zero*, thus showing how far below the average the cold of last year was. In the *Annales de la Société Météorologique*, vol. v., 1861, is a paper by M. Renou, "On the Periodicity of Great Cold." In this he shows that about every forty years there comes round a series of cold winters, in general five or six together, of which the central one is the coldest of all. His researches extend back to the fifteenth century, but to take recent times he notices the great frosts and cold winters which group themselves round the years 1709, 1748, 1789-90, and again in 1829-30. From these facts he predicted in 1860 that there would be a group of severe winters round the winter of 1870-71.

IN furtherance of the British Guiana Local Exhibition to be held in that Colony during the present year, the Committee of Correspondence has issued an address to the "Farmers and other Proprietors of the Soil," calling upon them energetically not only to aid the Exhibition by simply sending specimens of the products of the Colony to be seen, passed by, and forgotten, but to bear in mind how many useful products are lost to commerce through lack of continued exertions in the cultivation of the plants and the supply of the home market, and pointing out how that Exhibitions "can never be regarded as entirely satisfactory until additions are permanently made to the stock of commodities which are in daily use at home, as well as to the list of such as make the resources and the importance of the Colony known and esteemed in the markets of the world." British Guiana is a colony rich in natural productions, and it is to be hoped that the pamphlet will be read and digested by those to whom it is addressed.

ANOTHER tigress is recorded as dead in India, at the hands of Major Daires, of the Madras Presidency, and none too soon. She had, in seven years, killed above 140 persons in a few villages, so that many families had left, and a great part of the land had gone out of cultivation.

ON the 28th October two shocks of earthquake were felt at Shikarhera, in Upper Scinde. On the 1st November a severer shock was felt in the Tinnevelley district than ever had been known in the memory of man. The shocks were undulatory.

THE LONDON CONJOINT EXAMINING BOARDS

We reprint from the *British Medical Journal* the draft scheme of the committees of the Royal Colleges of Physicians and Surgeons, and the Society of Apothecaries, in the form in which it was presented to the College of Physicians at their Comitia and approved. In this form the scheme differs essentially from that of last year. This is no longer, as it now appears, a scheme for a minimum qualification for English practitioners, complete, unified, and preliminary in all respects to higher diplomas.

The following is the draft scheme :—

1. That one Board of Examiners, in the division of the United Kingdom, be appointed by the Royal College of Physicians of London, the Royal College of Surgeons of England, and the Society of Apothecaries of London, for the examination of candidates who desire to practise Medicine, Surgery, and Midwifery.

2. That candidates who shall have passed the several examinations of the Board be entitled, subject to the bye-laws of each institution, to the Licence of the Royal College of Physicians of London, the Diploma of Member of the Royal College of Surgeons of England, and the Certificate of the Society of Apothecaries of London.

3. That Examiners be appointed as follows ; viz. :

In Medicine, by the Royal College of Physicians and the Society of Apothecaries.

In Surgery, by the Royal College of Surgeons.

In Anatomy and Physiology, by the Royal College of Physicians and the Royal College of Surgeons.

In Midwifery, by the Royal College of Physicians, the Royal College of Surgeons, and the Society of Apothecaries.

In Materia Medica, Medical Botany and Pharmacy, Chemistry, and Forsenic Medicine, by the Royal College of Physicians and the Society of Apothecaries.

4. That the number of Examiners assigned to each subject be as follows, viz. : Anatomy and Physiology, not less than 8 ; Chemistry, Materia Medica, Medical Botany and Pharmacy, not less than 8 ; Medicine, not less than 10 ; Surgery, not less than 10 ; Forensic Medicine, not less than 4 ; Midwifery, not less than 6.

5. That the appointment of the Examiners in each subject be made by each of the three Corporations in the following proportion ; viz., Anatomy and Physiology—Royal College of Physicians, 3 ; the Royal College of Surgeons, 5. Chemistry, Materia Medica, Medical Botany and Pharmacy—the Royal College of Physicians, 4 ; the Society of Apothecaries, 5. Surgery—the Royal College of Surgeons, 10. Forensic Medicine—the Royal College of Physicians, 2 ; the Society of Apothecaries, 2. Midwifery—the Royal College of Physicians, 2 ; the Royal College of Surgeons, 2 ; the Society of Apothecaries, 2.

6. That there be two or more examinations on professional subjects, and that the fee payable for the examinations be thirty guineas, to be paid in two or more payments.

7. That one-half of the fees received for the examinations be appropriated to the payment of the examiners and the expenses of the examinations.

8. That the other half of the fees be divided amongst the three Corporations, upon the principle of giving to each Corporation a sum proportionate to that which each has respectively obtained from the grant of licences on the average of the last five years.

9. That the mode of division of the second half of the fees be subject to revision at the end of every three years.

ERNST HAECKEL ON THE MECHANICAL THEORY OF LIFE AND ON SPONTANEOUS GENERATION

In his recently published Biological Studies * Professor Haeckel, of Jena, has briefly stated his views on the question of Abiogenesis, which is now so largely occupying attention in England. He, having done more than any other observer to establish the Protoplasm theory by his discovery of organisms of the simplest conceivable structure—not even cellular (*i.e.*, not even possessing a differentiated central nucleus)—his remarks on the present condition of the Spontaneous Generation question must possess great weight. The philosophy of Monism, of which he is the exponent, as opposed to Dualism, rests on what he calls the Carbon theory and the Plastic theory. These theories are thus set forth in weighty, but clear sentences :—

1. The forms of organisms and of their organs result entirely from their life, and simply from the interaction of two physiological functions, Heredity and Adaptation.

2. Heredity is a part of the reproduction,—Adaptation, on the other hand, a part of the maintenance of the organism. These two physiological functions depend, as do all forms of vital activity, on the character of the physiological organ through which they come into play.

3. The physiological organs of the organism are either simple Plastids (Cytods or Cells), or they are parts of Plastids (*e.g.*, Nuclei of Cells, cilia of Protoplasm), or they are built up of numerous Plastids (the majority of organs).

In all these cases the forms and actions of the organs are to be traced back to the forms and actions of the individual Plastids.

4. Plastids are either simple Cytods (structureless bits of Protoplasm without nuclei) or Cells ; but since these last have originally arisen from Cytods by a differentiation of the inner "Nucleus" and the outer "Protoplasm," the forms and vital properties of all Plastids can be traced back to the simplest Cytods as their starting point.

5. The simplest Cytods, from which all other Plastids (Cytods and Cells) originally have arisen by Heredity and Adaptation, consist essentially and absolutely of nothing more than a bit of structureless Protoplasm—an albuminoid, nitrogenous Carbon-compound ; all other components of Plastids have been originally formed secondarily from Protoplasm (plasma-products).

6. The simplest independent organisms which we know, and which moreover can be conceived, the Monera, consist in fact while living of nothing else but the simplest Cytod, a structureless bit of Protoplasm : and since they exhibit all forms of vital activity (nutrition, reproduction, irritability, movement), these vital activities are here clearly bound on to structureless Protoplasm.

7. Protoplasm, or Germinal Matter (*Bildungsstoff*), also called Cell-substance or Primitive Slime (*Urschleim*), is therefore the single material basis (*materielle Grundlage*), to which without exception and absolutely all so-called "vital phenomena" are radically bound ; if the latter are regarded as the result of a peculiar Vital Force independent of the Protoplasm, then necessarily also must the physical and chemical properties of every inorganic natural body be regarded as the result of a peculiar force not bound up with its substance.

8. The Protoplasm of all Plastids is, like all other albuminoid or Protein-bodies, composed of four inseparable elements, Carbon, Oxygen, Hydrogen, and Nitrogen, to which often, though not always, a fifth element, namely, Sulphur, is added.

9. The forms and vital properties of Protoplasm are conditioned by the peculiar manner in which Carbon has

* A series of papers published originally in the *Jenaische Zeitschrift* during the year 1870, the author's Monograph of the Monera—for a translation of which see the Quart. Journal of Micr. Sci., 1869 ; also, the January No., 1871, where M. Haeckel's views on Coccoliths and Bathybius are noticed and illustrated in a plate.

combined itself so as to form a highly developed compound with the three or four other elements named. Compounds devoid of Carbon never exhibit those peculiar chemical and physical properties which exclusively belong to only a part of the compounds of Carbon (the so-called "organic compounds"); on this account modern chemistry has replaced the term "organic compounds" by the more significant term "Carbon-compounds."

10. Carbon, then, is that element, that indivisible fundamental substance, which, in virtue of its peculiar physical and chemical properties, stamps the various Carbon compounds with their peculiar organic character, and in chief fashions this Protoplasm, the "matter of life" (*Lebenstoff*), so that it becomes the material basis of all vital phenomena.

11. The peculiar properties which Protoplasm and the other component tissues and substances of the organism derived secondarily from it, exhibit, especially their viscid condition of aggregation, their continual change of matter (on the one hand their facile decomposition, on the other their facile power of assimilation) and their other "vital properties," are therefore simply and entirely brought about by the peculiar and complex manner in which Carbon under certain conditions can combine with the other elements.

12. The entire properties of the organism are, therefore, ultimately conditioned with equal necessity by the physical and chemical properties of Carbon, as are the entire properties of every salt and every inorganic compound conditioned by the physical and chemical properties of its component elements.

II.

We now pass on to the chapter in Haeckel's work headed "The Monera and Spontaneous Generation." Although, remarks Haeckel, Darwin himself states in his work that he has nothing to do with the origin of life, every thinking reader of the "Origin of Species" must ask himself whence came the simplest original living form? and no question has been more actively discussed, in consequence of Darwin's reform of the descent theory than that of spontaneous generation (*Urzeugung*). Abiogenesis (*Urzeugung*, which may best be translated as Archigenesis) is, in fact, a necessary and integral part of the universal evolution theory. It is the natural bridge which places in continuity Kant's and Laplace's theory of the mechanical origin of the universe and the earth, with Lamarck's and Darwin's theory of the mechanical origin of animal and vegetal forms. When we perceive that all inorganic nature, as well as the development of organic nature from an original parent organism, is explained by the continual working of one great law of evolution, we cannot admit in explanation of the one dark point in this great causal network a supernatural act of creation. We are logically bound to seek a natural link, and this link is Archigenesis (*Urzeugung*), *i.e.*, the origin of the simplest organisms from so-called lifeless inorganic materal. Till recently the question of Archigenesis has been treated by most naturalists in a most unphilosophical and superficial manner. Instead of examining the bearings of the question in all directions, and discussing duly its very complex nature, they have rushed into experiment, and obtained an answer without fairly putting the question. Because in highly artificial apparatus and under artificial conditions no organisms have been developed in certain fluids prepared for examination, the whole doctrine has been denied, and the totally unwarranted conclusion arrived at, "There is no Archigenesis." Such experiments as those of Pasteur and other very marvellous ones have really no value in this question, since they merely prove that in the particular case, under certain artificial and complex conditions, no organism is formed by Archigenesis. Positive contradiction of the hypothesis of Archigenesis is impossible. Positive proof there is not yet, since no one has yet seen any organism take origin, except by Parentage. But, thanks to our progress in biology during the last ten years, the question no longer presents the theoretical difficulties which it did. Before the discovery of those simplest of conceivable organisms, the Monera—it was necessary that from inorganic materials a Cell should be formed by Archigenesis—an organism presenting two chemically, physically, and morphological distinct portions, the inner Nucleus and the external Protoplasm. The formation of such a nucleated Plastid by Archigenesis is difficult to conceive. But now by the discovery of the Monera the matter assumes quite a different aspect. Such forms as *Protogenes* and *Protamœba* present no definite shapes, have no individual development, but grow and multiply by division. Their growth and nutrition is purely a physico-chemical process, just as the growth of a crystal, with this difference, that the viscid cohesion of Protoplasm entails intussusception of nutriment, whilst the crystal grows at its surface only. The same viscid state of cohesion explains the reproduction of such Monera—which we do not observe in crystals—the cohesive power of the Protoplasm under certain conditions of nutrition is no longer sufficient to hold the body together, and fission occurs. Thus the chief vital phenomena of Monera are traced to physico-chemical causes.

Since in our chemical laboratories, with our exceedingly limited and rough methods, we have succeeded in forming many Carbon-compounds, and have good reason to suppose that we may one day synthetically produce albuminoid bodies, is it not reasonable to suppose that in the great laboratory of Nature, similar but more complex chemical synthesis may go on, such as the formation from inorganic materials of albuminoids and of living protoplasm? If we are to call in a special creative act—superior to mere chemical synthesis—to account for the existence of Protoplasm because we have not succeeded in forming it artificially, so also must we postulate a peculiar creative act for a great variety of minerals, such as felspar, fluor spar, heavy spar, augite, &c., since we are equally unable to build up these inorganic bodies. In this way we should divide the whole world into a Natural and a Supernatural group. The former would contain such salts, gases, &c., as we can build up in the laboratory, also alcohol, acetic acid, &c. All these bodies have arisen by Archigenesis, *i.e.*, by natural, mechanical means, solely by the interaction of the inherent physical and chemical forces of their matter. The latter group would contain all minerals not yet formed in the laboratory, also all the complex Carbon-compounds. These bodies would be considered as arising by "Creation," that is, by supernatural means, through a mysterious creative force existing externally to the bodies.

To every philosophic naturalist such a view must appear as untenable as is every assumption of a "Creation." On the other hand the assumption of an Archigenesis for the first living beings from which all others have developed, is a logical postulate of the human intelligence.

It is not at all remarkable that as yet we have not observed the Archigenesis of Monera. Supposing it were taking place every day and every hour, it would be very difficult to observe. Very minute particles of Protoplasm are found in quantity, both in sea and fresh water, when carefully sought for. They are generally regarded as fragments of decomposing organisms. But what proof is there of this? and how could it be clearly proved that these particles have *not* arisen by Archigenesis? The first commencement of a Protoplasm-granule in a fluid would be as difficult to observe as the first commencement of a crystal in its mother-liquor. And not less difficult would be the observation of the gradual growth of such an excessively minute Protoplasm-granule into the larger protoplasmic masses of *Protamœba*, &c.

Bathybius seems to be of the greatest significance for the theory of Archigenesis. For if not through Archigenesis, whnce shall we derive this protoplasmic covering of the deepest sea-bottom?

Either the Monera were once for all, at the beginning of organic life on the earth, produced by Archigenesis—and hence—since Monera exist still to-day—they must have reproduced in a direct line unchanged for many million years; or, in the course of the earth's history, they have been produced by recurring acts of Archigenesis, and in this case there is no reason why this process should not occur at the present time. The latter view presents the fewest difficulties and exceptions to Prof. Haeckel. In any case the Monera still living at the present day point out to us the way to a correct understanding of the Origin of Life, and clear away the greatest difficulties which the hypothesis of Archigenesis previously presented. E. R. L.

SCIENTIFIC SERIALS

THE report of the meeting of Swiss Naturalists (*Schweizerische Naturforschende Gesellschaft*) in Solothurn on the 23-25 August, 1869, opens with an admirable presidential address on the progress of scientific investigation in Switzerland, by Prof. Lang. The reports of the sections contain numerous short notices of memoirs read, but among these are some of greater length and importance, such as a report by Dr. Hengi on his experiments in the culture of *Saturnia Yama-maya* and *S. mylitta*, a notice by M. F. Hermann on the use of Saussure's hair-hygrometer for scientific observations, a paper on creosote and other products by Prof. Völkel, a communication on fluorescence by Prof. Hagenbach, and a paper (printed in full) by Dr. von Fellenberg, containing analyses of some nephrites and jadeites, including a stone implement of the latter mineral from Möhringen-Steinberg, which he regarded as having been imported from the east. From his analyses of nephrites from different localities, it appears that they contain silica and magnesia in equal equivalents, but that the proportion of each of these to the lime varies as 7, 7½, 8, 9 : 3. Hence he regards them as forming not a definite mineral species, but a group of silicates of magnesia and lime formed by the metamorphosis of rocks of similar composition. He does not consider the nephrites allied to the amphiboles and augites. The memoirs include a report by Prof. Pictet de la Rive on the present state of the question as to the limits of the Jurassic and Cretaceous periods, a notice of which has already appeared in NATURE; an account of the Miocene Flora of Spitzbergen, by Prof. Oswald Heer; and a report on the investigation and preservation of the erratic blocks in Switzerland, by MM. A. Favre and L. Soret. An amusing account of the festal doings of the Society concludes the volume.

FROM the Natural History Society of Stralsund (Neu-Vorpommern) and Rügen, we have received the second annual part of their *Mittheilungen* containing the proceedings of the society for the year 1869. It contains a life and list of the works of Prof. A. E. Legnitz, by Prof. von Feilitsch; a description of the Island of Gottland, with a notice of the birds inhabiting it, by M. L. Holtz, unfortunately disfigured by some very absurd misprints; a notice on the proper heat of plants, by Dr. J. Romer, containing details of experiments made with *Philodendron pinnatifidum* Schott, from which it appears that the proper heat of this plant is much higher than stated by C. H. Schulz; and a paper (illustrated) on the itch-mites of fowls by Prof. Finsterberg. In the last-mentioned paper the author describes a species of mite inhabiting the feet of fowls, for which he proposes the formation of a new genus, *Knemidokoptes* (recte *Cnemidocoptes*). He names the species *K. viviparus*, as it produces living young.

THE last part of the *Archives Néerlandaises des Sciences Exactes et Naturelles à Harlem* for 1870 contains the following papers:—J. A. Groshaus on the Specific Heats of Solids and Liquids, which is a continuation of his former papers published in the same journal, in which he confirms Kopp's results in obtaining a constant when the specific heat of every substance is multiplied with its atomic weight, the constant being 6·3 to 6·5.—C. K. Hoffmann and H. Weijenbergh, jr., on the position of Chiromys (The Aye-Aye of Madagascar) in the natural classification. This is an elaborate memoir which was crowned by the society in 1869, and treats of all the characters in detail, their final decision being to make the following classification: Mammalia, Order ii. Quadrumana, Sub-order ii. Prosimiæ, Families: 1, Lemurini; 2, Nyeticebini; 3, Macrotarsi; 4, Microtarsi. The fourth family is distinguished by the tarsal bones more or less elongated (*allongés*), and by difference in the dentary systems, especially in the character of the incisor teeth. In common with Macrotarsi they have the tail, long large eyes directed in front, and large ears, and they feed chiefly on insects. Of this family two genera are given; Microcebus Geoff. and Chiromys Cuv., two species of the first one found in Madagascar, and one of the second, the common Aye-Aye.—M. G. F. W. Baehr gives a note on the Results of the Mathematical Study of the Movements of the Eye.—M. H. H. von Zouteveen on the Petrified Forest of Cairo, and by the same author on the Synthesis of Sulphocyanate of Ammonium.—M. Van der Willigen on Holtz's Electrical Machine.—M. A. C. Oudemans, jr., on the Volumetric Estimation of Iron by Hyposulphite of Sodium.—M. H. Weijenbergh, jr., on Parthenogenesis among the Lepidoptera.—M. C. Ritsema on the Origin and Development of *Periphyllus testudo* v.d.H.; and lastly a report on the Purification of the Air of Hospitals by the Combustion of the Organic Germs, by MM. J. van Genns and L. H. von Baumhauer. This is the report of an investigation undertaken at the instance of the Dutch Government to determine if the apparatus devised by M. Woestyn, of Paris, completely destroy all vital properties in the germs. They report that the apparatus contains nothing new, and that it does not effect its purpose any better than the ordinary methods in use.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 19.—"Modification of Wheatstone's Bridge to find the Resistance of a Galvanometer Coil from a single deflection of its own needle," by Prof. Sir William Thomson, F.R.S. In any useful arrangement in which a galvanometer or electrometer and a galvanic element or battery are connected, through whatever trains or network of conductors, let the galvanometer and battery be interchanged. Another arrangement is obtained which will probably be useful for a very different, although reciprocally related object. Hence, as soon as I learned from Mr. Mance his admirable method of measuring the internal resistance of a galvanic element (that described in the first of his two preceding papers), it occurred to me that the reciprocal arrangement would afford a means of finding the resistance of a galvanometer-coil, from a single deflection of its own needle, by a galvanic element of unknown resistance. The resulting method proves to be of such extreme simplicity that it would be incredible that it had not occurred to any one before, were it not that I fail to find any trace of it published in books or papers; and that personal inquiries of the best informed electricians of this country have shown that, in this country at least, it is a novelty. It consists simply in making the galvanometer-coil one of the four conductors of a Wheatstone's bridge, and adjusting, as usual, to get the zero of current when the bridge contact is made, with only this difference, that the test of the zero is not by a galvanometer in the bridge showing no deflection, but by the galvanometer itself, the resistance of whose coil is to be measured, showing an unchanged deflection. Neither diagram nor further explanation is necessary to make this understood to any one who knows Wheatstone's bridge.

Zoological Society, February 21.—Mr. Osbert Salvin, F.Z.S., in the chair. The Secretary announced the birth of a young Hippopotamus in the Society's Gardens, which had taken place that day, being the first occurrence of this event in England, although this animal had previously bred in some of the Continental Gardens.—Mr. Sclater exhibited and made remarks upon the tusk of an Indian elephant, which appeared to have been attacked by parasites.—The Secretary exhibited, on behalf of Mr. E. Ward, F.Z.S., a remarkably fine series of heads and horns of sheep and other wild animals, which had been collected in Ladahk by Mr. George Landseer.—A communication was read from Dr. W. Peters, F.M.Z.S., containing a note on the *Tænia* from the Rhinoceros, in reference to a previous communication from Dr. Murie, to the society, upon the same subject.—A communication was read from Mr. J. H. Gurney, F.Z.S., containing remarks on certain species of Abyssinian birds.—A communication was read from Dr. J. Anderson, C.M.Z.S., containing notes on certain Indian reptiles belonging to the collection of the Indian Museum, Calcutta.—A second communication from Dr. Anderson contained the descriptions of eight new species of birds, recently collected by him during the Yunan expedition.—A paper was read by Mr. W. C. Atkinson, containing descriptions of some new species of Diurnal Lepidoptera, discovered in Yunan by Dr. Anderson during the same expedition.—The Secretary communicated a paper by Mr. Edward Bartlett, containing observations on the habits and distribution of the monkeys of Eastern Peru, as observed during a recent four years' sojourn on the Upper Amazons.

Geological Society, February 8.—Mr. Joseph Prestwich, F.R.S., president, in the chair. 1. "On the Punfield Formation," by Mr. John W. Judd. Those formations, which have been deposited under *fluvio-marine* conditions, and which yield at the same time marine, fresh-water, and terrestrial fossils, are of especial interest to the geologist, as they furnish him with a means of correlating the great fresh-water systems of strata with those of marine origin. At the bottom of the Wealden we have one such fluvio-marine series, the well-known Purbeck formation; at its summit is another, less known, but not less important, for which the name of "Punfield Formation" is now suggested. Some of the fossils of the latter were first brought under the notice of geologists by Mr. Godwin-Austen in 1850, and their peculiarities have since been the subject of remark by Prof. E. Forbes, Sir C. Lyell and others. The typical section of the beds is at Punfield Cove, in the Isle of Purbeck, where they are about 160 feet thick, and include several bands with marine shells. The lowest and most remarkable of these yields about forty well-defined species, many of which, as well as one of the genera, are quite new to this country. A section somewhat similar to that of Punfield is seen at Worborrow Bay. In the Isle of Wight, at Compton, Brixton, and Sanddown Bays, similar fluvio-marine beds are found at the top of the Wealden, and attain to a thickness of 230 feet. The marine bands here, however, yield but a very scanty fauna. Indications of the existence of beds of the same character and in a similar position are found in the district of the Weald. While the Purbeck formation exhibits the gradual passage of the marine Portlandian into the freshwater Wealden, the Punfield formation shows the transition of the latter into the marine Upper Neocomian (Lower Greensand). Thus we are led to conclude that the epoch of the English Wealden commenced before the close of the Jurassic period, lasted through the whole of the Tithonian and of the Lower and Middle Neocomian, and only came to a close at the commencement of the Upper Neocomian. In tracing the Cretaceous strata proper from east to west, they are found to undergo great modification, while the Neocomian and Wealden, which they overlap through unconformity, besides being greatly changed in character, thin out very rapidly. On stratigraphical and palæontological evidence, the Punfield formation is clearly referable to the upper part of the Middle Neocomian. Its fauna has remarkably close analogies with that of the great coal-bearing formation of eastern Spain, which is of vast thickness and great economic value. The claim of the Punfield beds, equally with the similarly situated Purbeck series, to rank as a distinct formation, is founded on the distinctness of their mineralogical characters, their great thickness, the fact of their yielding a considerable and very well characterised fauna, and of their being the equivalent of a highly important foreign series. The president remarked that the limited amount of fresh-water formations in this country was an obstacle to their correlation, and stated that Constant Prevost had endeavoured to correlate the secondary fresh-water and marine formations. Mr. Godwin-Austen remarked upon the thinning out of the Lower Greensand, especially in France; upon the imperfection of our knowledge of the great Cretaceous formation, and upon the probability of the intercalation of fresh-water conditions in the Lower Greensand. The formation at Punfield seemed to present an intercalation of marine between purely fresh-water conditions. He indicated how a slight change of level might have intercalated marine conditions in the Wealden. The deposition of the White Chalk and Oolite occupied enormous periods (in both cases purely marine), during which the northern hemisphere was a great northern ocean; and as the distribution of land and water was due to the operation of great cosmical laws, the duration of terrestrial and of the intermediate freshwater conditions was probably of equal length. Mr. Judd, in reply, said that he did not propose the term Punfield formation as a definitive term, but only as a matter of convenience. He believed that strata could be positively identified by he organic remains contained in them, although the method may have been grossly abused. Physical investigations alone led to nothing but confusion, as might be seen by the stratigraphical attempts of the predecessors of William Smith. The name *Vicarya* for the shell which had been referred to was only provisionally adopted, on the authority of De Verneuil and other writers. 2. "Some remarks on the Denudation of the Oolites of the Bath district, with a theory on the Denudation of Oolites generally." By Mr. W. S. Mitchell. The author briefly referred to the theory according to which oolitic deposits were supposed to have been originally spread out in continuous sheets over the country which they occupy, and to owe their division into separate hills to the action of denudation after their original deposition and consolidation. He suggested, as an equally probable hypothesis, that whilst the marls and clays of oolitic areas were probably originally deposited in continuous beds, the limestones in many cases may never have extended beyond the areas now occupied by them. He described the beds of limestone in the oolitic hills as thinning out towards the valleys on all sides, maintained that the limestones owed their origin to coral reefs, and cited several descriptions of coral islands by Prof. Jukes, to show the agreement in their structure with that which he ascribed to the oolitic hills. He assumed that in the event of a coral-area becoming one of sedimentary deposition, the sedimentary deposit would preserve intact the contour of the coral islands, and inferred that this has been the case in the Bath district, so that the Great Oolite cappings of the hills of that area may represent the original contours of coral islands, exposed by the denudation of the Bradford clay. The amount of denudation undergone by the Great Oolite limestone he considered to be very small. The Inferior Oolite, on the contrary, he believed to have suffered denudation, and he considered that the course of the valleys formed by this agent was dependent on the form of the limestones capping the hills. Prof. Morris did not consider that the author's views as to the oolitic masses round Bath being originally isolated coral banks with clay beds, although suggestive, were quite satisfactory. He pointed out that the strata on each side the valleys were similar in structure, mineral character, and fossil contents, and were once continuous; and the present intervening deep valleys were rather due to the movements which the area had undergone in producing lines of weak resistance, subsequently assisted by the erosive action of percolating and running water, both in excavating and undermining the harder rocks, so as to cause them to bend towards the hill-sides, or fall in larger or smaller masses on their slopes. Mr. Mitchell, in reply, stated that he had seen both sides of what he regarded as coral reefs. He remarked that his hypothesis was arrived at by deduction, by inferring from observations on existing coral-reefs that those of the Oolites must have been covered up as islands. He remarked that if the oolitic beds had slipped, as described, upon the underlying clays, they could hardly range on opposite sides of the valleys. He noticed that the action of water in covering the blocks of Oolite with crystallised carbonate of lime would be protective, and remarked that the surface of the reefs was virtually a sea-bottom on which mollusca lived, so that their occurrence at corresponding levels in different hills was not to be wondered at.

February 17.—Mr. Joseph Prestwich, F.R.S., president, in the chair.—The Secretary read the reports of the Council, of the Library and Museum Committee, and of the auditors. The general position of the Society, as shown by the state of its finances and the continued increase in the number of Fellows, was said to be very satisfactory. In presenting the Wollaston Gold Medal to Prof. Ramsay, F.R.S., F.G.S., the President spoke as follows—"Prof. Ramsay,—I have great pleasure in presenting you with the Wollaston Medal, which has this year been awarded to you by the Council of the Society, in recognition of your many researches in practical and in theoretical geology. Distinguished as your services have been in connection with the Geological Survey since you entered upon it as the Assistant Geologist of Sir Henry De la Beche in 1841, and more particularly since your appointment as Local Director in 1845, during which period you have superintended and carried out the admirably minute style of mapping now general on the survey, and done so much in training its members in the field, you have not less distinguished yourself by your investigations of the higher problems involved in the study of geology. Your first work was on the Isle of Arran; and although then only a beginner, you, instead of taking the rocks to be what they looked, worked out what they were, and gave a new and independent reading of them, which has since in great part proved to be the right one. In 1846 your well-known memoir, 'On the Denudation of South Wales and the adjacent Counties of England,' showed the enormous amount of denudation that the Palæozoic rocks had undergone before the deposition of the New Red Sandstone. At subsequent periods you dwelt on the power that produced 'Plains of Marine Denudation,' a term introduced, I believe, by yourself, and showed in all cases, by a series of true and beautiful sections, how this has operated in planing across the older strata, and how valleys had been scooped out by subsequent aqueous causes in the great plains so formed. Whilst unravelling the complicated interior phenomena of the Welsh rocks, you were not unmindful of the very different order of phenomena exhibited on their exterior surfaces. Here you showed the vast extent and power of ice-action, and what a glacier land Wales once was. Reasoning from the present to the past, you also boldly pushed your ice-batteries far back into geological time, and were the first to bring them to bear on rocks of Permian age. That advanced post you long had to hold alone; but other geologists have since followed your lead, and we have even lately had evidence in the same direction from Southern Africa, where it is asserted that boulders and glaciated surfaces have been found at the base of the Karoo formation of supposed Jurassic age. You have also held a prominent place among those who, by their public teaching, have done so much during the last twenty years to advance the cause of our science. To myself, personally, whose geological career has run nearly parallel in time with your own, it is a source of much pleasure that it has fallen to my lot to hand you this, the highest testimonial the Society has to bestow."—Prof. Ramsay made the following reply:—"Mr. President,—I cannot say whether I am more pleased or surprised by the unexpected award to me of the Wollaston Medal by the Council of this Society. Pleased I well may be, not because I ever worked for this or any other honour, but because I feel a sense of satisfaction that the work on which I have been engaged for the last thirty years has been esteemed by my friends and fellows of the Council of the Society so highly, that they have deemed me a fit recipient of this honour. It is also a special satisfaction to me that this award has been bestowed by the hand of one of my oldest geological friends, who is so universally esteemed and beloved, and is himself so distinguished a contributor to physical and other branches of our science. My first endeavour in geology (the conconstruction of a geological map and model of Arran) necessarily drew my attention to the physical part of our science; and when, consequent upon that work, I was, through the intervention of my old and constant friend, Sir Roderick Murchison, appointed by Sir Henry De la Beche to the Geological Survey of Great Britain, my whole subsequent life was thereafter necessarily involved in questions of physical geology, for no man can work on or conduct the field-work of such a survey who does not, aided by palæontology, necessarily make that his first aim. If some of my theories, induced by that work, were long in being recognised, the recognition has been all the more welcome when it came. Probably I never should have been able to do what I have done but for the wise example of my old master, Sir Henry himself, in his time the best thinker in England on the physical branch of our science, and to whose remarkable work, 'Researches in Theoretical Geology,' all geologists are to this day indebted. The papers which I have written are mere offshoots from my heavier work on the Geological Survey. Perhaps they are enough for the readers; but I wish they had been more numerous, for I certainly have had many more in my mind. Two of these, on old physical geographies of the world, I have lately given to the Society; and if they should be printed, I shall be well pleased should they soon or late be found worthy. The present physical geography of the world is but the sequel of older physical geographies; and to make out the history of these is one of the ultimate aims of geology. These are the subjects I have striven to master in part. I consider your award as a sign that I have had some success; and if, before I cease to work, I have a little more, I may be well content."—The President then presented the Balance of the Proceeds of the Wollaston Donation Fund to Mr. Robert Etheridge, F.G.S., in aid of the publication of his great stratigraphical "Catalogue of British Fossils," and addressed him as follows:—"Mr. Etheridge,—The Council of the Society has awarded to you the Proceeds of the Wollaston Fund, to aid in prosecuting your valuable work on the fossils of the British Islands, stratigraphically arranged. In this work, on which you have been engaged during the last eight years, and which occupies nine volumes of MS., representing as many geological groups, you give the natural history lists of each group, and trace the history of each species both in time and space. Of the magnitude of the work few can have any idea, nor would many have an idea of the marvellous extent of past life in our small portion of the globe without a comparison of our recent fauna with those (necessarily incomplete, because only partly accessible) which you have enumerated in your most useful lists. This comparison shows:—

	Polyzoa. Zoophytes. Echinoderms.	Crustacea.	Mollusca.	Fishes.	Reptilia.	Birds.	Mammalia.	Plants.	Total.
Number of Species in the existing fauna and flora of Gt. Britain	616	278	567	263	15	354	76	1820	3,989
Number of Species found fossil in Gt. Britain . . .	2574	746	7091	815	224	12	172	819	12,453

I trust that this work will not be allowed to remain in MS., and that, presuming you will begin with the oldest, we may soon look for an instalment in the fauna of the Palæozoic rocks. I have much pleasure in presenting you with this token of the importance which the Geological Society attaches to your labours." —Mr. Etheridge made the following reply:—"I have great satisfaction in receiving from you, Sir, and the Council of the Geological Society, the award of the Wollaston Fund. It is given for work known to be nearly done, and faith in its completion. The time and labour devoted to my book upon the 'Stratigraphical Arrangement of the British Fossils' has extended over nearly nine years of incessant work, and has been an arduous, yet pleasant undertaking, now made lighter by the recognition of those who know and value the researches made for so extensive a catalogue of the British organic remains, now numbering nearly 13,000 species. It is this estimation of my labour by the Council and Society that tends to increase the desire to make my work as perfect as possible, well knowing how difficult, if not impossible, it is to do so. This acknowledgment, Sir, from your hands will stimulate me to finish my researches into the literature of the British species, and their history through space and time throughout Europe."—The President then proceeded to read his anniversary address, in which he discussed in considerable details the bearing of the recent deep-sea dredging operations upon geological reasoning. The address was prefaced by biographical notices of deceased fellows, including Sir Proby Cautley, Sir Frederick Pollock, Mr. Robert Hutton, and Prof. Gustav Bischoff.—The ballot for the Council and Officers was taken, and the following were duly elected for the ensuing year:—President: Joseph Prestwich, F.R.S.. Vice-presidents: Sir P. de M. G. Egerton, M.P., F.R.S., Prof. T. H. Huxley, F.R.S., Sir Charles Lyell, Bart., F.R.S., Prof. John Morris. Secretaries: John Evans, F.R.S., David Forbes, F.R.S. Foreign Secretary: Prof. D. T. Ansted, F.R.S. Treasurer: J. Gwyn Jeffreys, F.R.S. Council: Prof. D. T. Ansted, F.R.S., Dr. W. B. Carpenter, F.R.S., William Carruthers, W. Boyd Dawkins, F.R.S., Prof. P. Martin Duncan, F.R.S., Sir P. de M. G. Egerton, Bart., F.R.S., John Evans, F.R.S., David Forbes, F.R.S., J. Wickham Flower, Capt. Douglas Galton, C.B., F.R.S., R. A. C. Godwin-Austen, F.R.S., J. Whitaker Hulke, F.R.S., Prof. T. H. Huxley, F.R.S., J. Gwyn Jeffreys, F.R.S., Sir Charles Lyell, Bart., F.R.S., C. J. A. Meyer, Prof. John Morris, Joseph Prestwich, F.R.S., Prof. A. C. Ramsay, F.R.S., R. H. Scott, F.R.S., Prof. J. Tennant, Rev. Thomas Wiltshire, Henry Woodward.

London Mathematical Society, Thursday, Feb. 9.—Mr. W. Spottiswoode, President, in the chair. Mr. C. R. Hodgson, B.A., was proposed for election, and the Rev. J. Wolstenholme and Mr. R. B. Hayward, of Harrow, were elected members. Prof. Cayley made a communication "On an Analytical Theorem from a New Point of View," and also a second communication "On a Problem in the Calculus of Variations." The problem is, $z = \frac{1}{3}(3x - y^2)y$, to find y a function of x such that $\int z\,dx =$ maximum or minimum, subject to a given condition $\int y dx = C$ (the limits of each integral being $x_1\ x_0$ where these quantities are each positive, and $x_1 > x_0$). The ordinary method of solution gives

$$y^2 = x + \lambda, \text{ for}$$

$$\text{where } (x_1 + \lambda)^{\frac{3}{2}} - (x_0 + \lambda)^{\frac{2}{3}} = \tfrac{3}{2}\,C.$$

So long as c is not less than $(x_1 - x_0)\,\frac{3}{2}$, there is a real value of λ, but for a smaller value of c there is no real value. The difficulty arising in this last case is somewhat illustrated by replacing the original problem by a like problem of ordinary maxima and minima; viz., $x_1, x_2, \ldots x^n$ being given positive values of x, in the order of increasing magnitude—and if in general

$$z_i = \tfrac{1}{3}\,(3x_i - y_i^2)\,y_i,$$

then the problem is to find y_i a function of x_i, such that Σz_t = max. or min., subject to the condition $\Sigma y_i = c$. We have here $y_i^2 = x_i + \lambda$, where λ is then to be determined by the condition $\Sigma y_i = c$; the remainder of the investigation turns on the question of the sign

$$y_i = +\sqrt{x_i + \lambda} \text{ or } y_i = -\sqrt{x_i + \lambda}$$

to be taken for the several values of i respectively.—Prof. Henrici exhibited a plaster model of a tubular surface of the 6th order, which may be generated in either of the two following modes. Either a sphere of constant radius moves with its centre on a parabola, or it rolls along the same parabola always touching both its branches. The two envelopes thus produced differ in position only. The second mode of generation shows that the surface has a nodal curve, which is a parabola congruent to that on which the centre of the sphere moves; but in a plane perpendicular to it. Through a part of it only do real sheets of the surface pass. There is also a cuspidal curve of the 6th order, which has two cusps. The nodal curve passes through them, and has at these cusps the same tangents. The equation to the surface is

$$(27\,py^2 + 9\,x\,K - x^3)^2 = (x^2 + 3K)^3$$

where

$$K = (x + 2p)^2 + y^2 + z^2 - r^2$$

r = radius of the sphere and $4p$ is the parameter of the parabola. The equations to the parabola, on which the centre of the sphere moves, are

$$y^2 = 4p\,(x + 2p),\ z = 0;$$

those of the nodal curve,

$$y = 0,\ z^2 = -4px + r^2 - 4p^2;$$

the equations to the cuspidal curve are

$$27py^2 - 4x^3 = 0,\ x^2 + 3k = 0;$$

the first is a cylinder, which cuts the plane $z = 0$ in the evolute of the parabola, the second represents an ellipsoid of revolution. The model was constructed to the scale

$$p = \tfrac{1}{20},\ r = 2 \text{ inches.}$$

It was agreed, on the suggestion of Dr. Hirst, that Prof. Henrici should order a second model to be cast for the use of the society. Mr. Merrifield, F.R.S. laid the following statement before the society. "If the equation of a surface be

$$Z = F(x\,y) \tag{1}$$

it is very well known that the condition that it should be a ruled surface is that

$$\left(\lambda \frac{d}{dx} + \mu \frac{d}{dy}\right)^2 z \tag{2}$$

and

$$\left(\lambda \frac{d}{dx} + \mu \frac{d}{dy}\right)^3 \tag{3}$$

should have a common factor of the form $A\lambda + B\mu$; and also that the condition of its being developable is that (2) should have two equal factors of that form. I have found upon actual trial that for a conical surface (3) will have two equal factors, and for a cylindrical surface, three equal factors; that is to say, if we write, $\alpha = \dfrac{d^3z}{dx^3}$, $\beta = \dfrac{d^3z}{dx^2dy}$ &c., we have for a conical surface

$$(\alpha\,\delta - \beta\,\gamma)^2 = (\alpha\gamma - \beta^2)\,(\beta\,\delta - \gamma^2)$$

and for a cylindrical surface we have separately

$$(\alpha\,\delta - \beta\,\gamma) = 0,\ (\alpha\,\gamma - \beta^2) = 0,\ \beta\,\delta - \gamma^2 = 0$$

If, following Monge, we regard the surface as traced out by a right line moving on three director curves, the condition of two or three equal roots is evidently the same as that, out of the three characteristics passing through a point, two or three should become coincident. I have not yet had time to look into the question whether the converse of the proposition is true, viz., whether the introduction of the condition of developability ($rt = s^2$) necessarily reduces the surface, in which two or three of the characteristics coincide, to a cone or cylinder." The president and members present expressed their wish that Mr. Merrifield would be able to find time for the consideration of this converse proposition. Dr. Hirst then made some remarks on the connection between the correlation of two planes, as described in his last communication to the Society, and Sturm's solution of the problem of projectivity, as given by him in his memoir on the subject, published in the *Mathematische Annalen*, Vol. i., p. 533.

Linnean Society, February 16.—Mr. G. Busk, Vice-president, in the chair. Dr. J. D. Hooker presented to the Society on behalf of a committee appointed for the purpose, a half-length portrait of the President, Mr. G. Bentham, the expense of which had been defrayed by a subscription raised among the fellows of the Society. The following papers were then read, the interest of which was purely technical:—On Tremellineous Fungi and their Analogues, by L. and C. Tulasne; Bryological Remarks by Dr. S. O. Lindberg.

Entomological Society, February 20.—Mr. A. R. Wallace, president, in the chair. Mr. Bond exhibited a hybrid between *Bombyx Pernyi* and *B. yama-mai*, two of the larger silk-worm moths; this individual was of the colour of the one parent with the form of the other. He also exhibited an example of *Bombyx mori*, bred by Dr. Wallace, still retaining the larval head. Mr. McLachlan called attention to the first-recorded instance of a similar arrest of development, being a paper by O. F. Müller in "Der Naturforscher" for 1871. Mr. Smith mentioned that a common Egyptian wasp, *Rhynchium brunneum*, obliterated, by its nest, the inscriptions on the ancient monuments in that country; and he exhibited an example of the same wasp which had been found in the folds of the covering of a mummy, showing that the same species had inhabited Egypt for many ages. Mr. Smith further alluded to a passage in Pepys's Diary, dated May 1665, in which the writer narrated how he had seen a glass-hive where the bees could be seen at work, proving that observatory hives were not a modern invention. Mr. Müller read a paper "On the Dispersion of Non-migratory insects by Atmospheric Agencies," in which he had collected together a number of records of showers of insects after violent storms, and at sea at long distances from land; and he was of opinion that these agencies played a considerable part in the geographical distribution of insect life, though, no doubt, in many cases, the species thus involuntarily dispersed died out from inability to cope with the pre-existent denizens of the localities to which they were driven. Mr. H. Jenner-Fust communicated a supplement to his treatise on the geographical distribution in these islands of the indigenous Lepidoptera.

Dublin

Royal Irish Academy, Feb. 13—Rev. J. H. Jellett, B.D., president, in the chair.—Dr. Ferguson read a paper "On the Difficulties attendant on the Transcription of Ogham Legends, and the Means of Avoiding them." Leave was given to Mr. Charles E. Burton to read notes "On the Results obtained by the Agosta Sicily Expedition to Observe the recent Solar Eclipse."—A paper was read by Profs. W. King and T. H. Rowney, "On the Geological and Microscopical Structure of the Serpentine Marble or Ophite of Skye."—Papers "On Eozöon Canadense," by Principal Dawson, and on Messrs. King and Rowney's paper "On Eozöon Canadense," by Dr. T. S. Hunt, were deferred to the meeting of the 27th inst. when the discussion of all the papers on this subject will be taken.—Rev. President Henry, D.D., Belfast, H. Dix Hutton, LL.B., and T. W. Ellison Macartney were elected members of the Academy, and Prof. Traquair was admitted a member.—Sir W. Wilde presented on behalf of the Earl of Mayo, a collection of ancient Indian Coins, for which the marked thanks of the meeting were voted.

Hobart Town

Royal Society of Tasmania, October 11, 1870.—His Excellency, C. Du Cane, Esq., President, in the chair. The Secretary read some "Notes on an experiment with the fumes of sulphur, and of other methods for the destruction of rabbits in their burrows," by W. Archer, Esq., F.L.S. The fumes were forced into a burrow by means of bellows, attached to a receptacle in which the sulphur was burned; and that this was effectually done was proved by the escape of sulphurous vapour from the bolt-holes. When the burrow was afterwards opened, however, no trace of the fumes was left, nor were the animals destroyed. The experiment was recorded as a "guide or warning to others who may be induced to try further experiments with the fumes of sulphur, or with any other vapour." (Carbonic acid gas would not become condensed, and it would be fatal to animal life, but its use would probably be much too expensive). Mr. Abbott read a paper "On the Sun and its Office in the Universe." Some discussion of a conversational character having taken place, Mr. M. Allport begged to call the attention of the meeting to the fish presented by Mr. Wise (presentation No. 8), on account of its high scientific importance, as furnishing a complete answer to the theory raised by Dr. Günther in reference to the salmon first sent to England. The Doctor then assumed that the fish sent was hatched from one of the eggs imported to England in 1866. This assumption was met by the statement that the fry unnaturally detained in fresh water had reached a higher state of development than the smolt sent to England, and as the fish now presented was but just assuming the smolt stage, all the arguments used in reference to the smolts first caught apply with tenfold force to this specimen. It was, moreover, fortunate that they had in the Museum one of the fry hatched from the English eggs received per *Lincolnshire* in 1866, and which died in the spring of 1867. Upon comparing this with the fish now caught, it would be found that they accorded with one another so closely, as to leave little doubt of their identity in species. No report had yet been received from England as to the smolt last sent, though they had heard of its safe arrival. Mr. Allport further observed that Mr. Youl, in writing to Sir Robert Officer, had expressed a wish that the Salmon Commissioners should make it publicly known that after careful examination he entirely concurred with Dr. Günther in the opinion that the specimen first sent to England was a Salmon trout (*Salmo trutta.*)

BERLIN

Royal Prussian Academy of Sciences, June 2, 1870.—Prof. G. Rose communicated a long and elaborate memoir on the connection between the hemihedric crystalline form and thermo-electrical properties in iron-pyrites and cobalt-glance, with some remarks on the theory of hemihedric forms in general; and Prof. Dove read a paper on the reference of the annual curve of temperature to the conditions upon which it depends.

June 16.—M. Kummer read a paper on the simplest representation of the complex numbers formed from unitary roots, which can be effected by multiplication with unities. Prof. W. Peters read a description of *Propithecus Deckenii*, a new species of Lemuroidea from Madagascar; it is the species which had previously been identified by him with *P. diadema* Bennett.

June 23.—A paper was read on the Morphology of *Chonidriopsis cærulescens*, Crouan, and the optical phenomena presented by that Alga, by Dr. Leopold Kny. The author described in some detail the peculiar cell development and mode of ramification of the plant, and noticed more briefly the structure of the reproductive organs. The peculiar colour presented by the plant is produced by the contents of the outermost cortical layer of cells, and is due to the presence in them of certain corpuscles which have the faculty of reflecting blue light. Prof. du Bois Reymond read a supplement to his memoir on the aperiodic movement of muffled magnets.

June 27.—Prof. C. Rammelsberg read some contributions to the knowledge of meteorites. He first communicated some remarks on the analysis of meteorites, relating to a more recent process for the separation of nickel from iron, to the separation and determination of meteoric iron in stony meteorites, and to the analysis of the silicates, and then furnished analyses of meteoric irons, of the pallasite of Brahin, and of the chondrites of Pultusk, Richmond, and Iowa. His analyses of these chondrites and of that of Klein Wenden, lead him to the conclusion that they all contain only two silicates, olivine and broncite, a result which he finds to be confirmed by other analyses, and he affirms, that mesosiderite and chondrite do not differ petrographically but only in structure.

THE TEMPLE MEMORIAL AT RUGBY

WE hear with peculiar satisfaction that one of the memorials of the Bishop of Exeter at Rugby is to be an Observatory. It is a very appropriate memorial to a man who, above most others, recognised the true relations of science and literature, and did so much to give science its rightful place. And it is a valuable addition to the resources of a school; at present perhaps it will not find its full use; but when it does it will be well associated with the name of one who has foreseen the future position of our great public schools.

Our great public schools fulfil two functions, they prepare for the universities, but they are themselves the universities for the great majority of the boys who go to them; those who go into business, into the army, and to many other occupations, do not in general go to Oxford or Cambridge. Their school education ends at eighteen. Now this large class is scarcely sufficiently contemplated at schools. For them it is necessary that a school should offer, not the first part of an education which requires many years to complete it, but the best education that can be given where this limit of age is imposed. For such boys as these it is highly desirable that their school course should have more elevation about it, and more of practical application. It would take us far from our present subject if we were fully to develop our meaning; but it seems a step, and an important one, in the right direction, to establish an astronomical and meteorological observatory at one of the public schools; for this is to assert that such knowledge of these subjects as is attainable ought to be within reach of boys who will not have the opportunity of studying them after complete mathematical training at the universities. It is one step further towards establishing the ideal education, the co-existence of religious influence, literature, science, art, and handicraft in the same institution.

Some amount of astronomical teaching is necessary in a school; it is very much neglected at present, because it does not pay in examinations. Yet we know by experience that few subjects are so interesting as astronomy. And in schools, as at Rugby, where geometry and mechanics are taught, the noblest illustrations may be taken from the mechanism of the heavens. But astronomy cannot be taught by a book only. The most useful, indispensable instrument to an astronomical teacher is an orrery. No descriptions, no diagrams, give boys a conception of the solar system so clearly as a few minutes with an orrery. The next most useful instrument is a telescope. And certainly Rugby seems to be fortunate in the instrument that is to be given to it.

The Temple Telescope is a noble one. The object-glass, of $8\frac{1}{4}$in., was made with especial care and pains by Alvan Clarke for Mr. Dawes. It is $8\frac{1}{4}$ inches aperture, and $108\frac{3}{4}$ focal length. It is mounted equatorially, has an excellent driving clock, of an unique kind; and the eye-pieces range from 92 to 1,000.

An instrument like this is, of course, a luxury, but its beauty is, in itself, a great inducement to its use. There are few things so wondrously beautiful as the moon, or Jupiter, or a star cluster, seen with a low power in such a telescope. And any one who has tried to show the moon to several people with an ordinary telescope will appreciate the advantage of having it equatorially mounted, and of its being provided with a driving clock.

Other instruments for astronomy, surveying, and meteorology, will be added to the observatory; some of the masters having provided a fund adequate to give so fine an instrument all the surroundings that are required to make it practically available. And ere long we hope to see a really useful observatory established.

It is to be under the joint management of Mr. Wilson, who munificently gives the telescope, and Mr. Seabroke, an old Rugbeian, who is already favourably known as a worker. He still has his spurs to win, however, and will soon be very favourably situated for winning them.

The telescope is now the property of the Rev. H. E. Lowe, of Atherstone, but will become the property of Mr. Wilson in March. We greatly regret to hear that circumstances which have lately happened at Rugby affecting the tenure of masterships will prevent for the present the gift of the observatory to the school, and can only hope that it will not be long before the present difficulties are overcome. Meantime it will be established on private ground, and will be accessible to the school. Verily there be head-masters and head-masters, and masters and masters!

L.

THE EXPERIMENTAL AND NATURAL SCIENCES IN TRINITY COLLEGE, DUBLIN

THE condition of the Experimental and Natural Sciences in the various Universities is at the present time a subject of such general interest that we give the following sketch of what is now done for them in Trinity College, Dublin.

Until a student passes the Michaelmas term examination of his second (Senior Freshman) year he is supposed to confine his attention to classics, mathematics, and logic; but in his third and fourth years he must devote himself, to a certain extent, to the study of Experimental Physics, including heat, electricity, magnetism, and chemistry, and pass examinations on these subjects even at the ordinary term examinations. In the fourth year of his studies the student can go in for honours in Natural and Experimental Sciences, the course for which includes Jamin's "Cours de Physique," Lloyd's "Wave Theory of Light," Naquet's "Principles of Chemistry," Cotta's "Classification of Rocks," and Haughton's "Manual of Geology."

At the conclusion of his collegiate studies the student can graduate in either Experimental or in Natural Science, and the Court of Examiners can recommend the most distinguished of the candidates to the Board for gold and silver medals; candidates thus recommended receiving their B.A. degrees as Senior and Junior Moderators respectively.

The subjects for examination for the Moderatorships in Experimental Science are (1) Experimental Physics viz., Heat, Light, Sound, Electricity, and Magnetism; (2) Chemistry, Inorganic and Organic; (3) Mineralogy, including Crystallography; and the hundred marks allotted to the examination are as follows:—Light and

Sound, 20; Heat, Electricity, and Magnetism, 30; Inorganic and Organic Chemistry, 15 each; Mineralogy and Crystallography, 10 each. It need only be added that lectures on all these subjects are delivered every term by the respective Professors.

The subjects of examination for the Moderatorship in Natural Science are the following, each of which has equal weight:—(1) Physiological and Comparative Anatomy; (2) Zoology and Botany; (3) Geology (including Physical Geography and Palæontology).

It may be objected that the distinction between Zoology and Comparative Anatomy will not hold good, and the books ordered to be read under both sections seem to demonstrate this. But there can be little doubt that the establishment of this Moderatorship is a step in the right direction, and the course is such that every medical student ought to take it up and do his utmost to attain a place among the golds.

It is of course not to be denied that there are no scholarships, no studentships nor fellowships to be attained by a knowledge of these sciences, but perhaps even these may in time come. It is not so very long ago when a student could aspire to but few distinctions if he were not a first-rate mathematician; now this is completely altered, and as the world rolls on changes come with it.

The chemical and physical laboratories of the College leave nothing to be desired. The distinguished Medical Registrar takes care that there shall be every facility given to students to work out the Comparative Anatomy of the Vertebrates, and places at the disposal of the College the animals that from time to time die in the Zoological Gardens. The Professor of Zoology demonstrates the Anatomy of the Invertebrates to his class during two out of the three terms. The Botanical Gardens and the Herbarium are as extensive as any University can require, and there are two courses, one of forty and another of twenty lectures, delivered each year in Botany, besides garden demonstrations.

In conclusion we venture to suggest that if the M.D. degree should only be taken by the reading and publishing of a Thesis, as in some of the German Universities, it would help materially to assist the cause of the Sciences in Trinity College, Dublin; for, though some of the candidates might select practical subjects, others, doubtless, would turn their attention to the wide fields of Zoology and Botany. W.

SIR JOHN LUBBOCK ON THE ORIGIN OF CIVILISATION

The Origin of Civilisation and the Primitive Condition of Man: Mental and Social Condition of Savages. By Sir John Lubbock, Bart., M.P., F.R.S., &c. (Longmans, 1870.)

NOW that Sir John Lubbock's work on the "Origin of Civilisation" has reached a second edition, it is perhaps only natural that those who make it their business to warn the public against the encroachments of Science should raise an alarm against the first. In a recent number of the *Christian Advocate and Review* appears, accordingly, an article specially devoted to the demolition of Sir John's theories, and the vindication of human degeneracy. With the felicitous instinct of clerical antagonism, the Advocate and Reviewer makes his fiercest onslaught precisely where his opponent happens to be least vulnerable, and lays about him with all the fine, fervid imbecility distinctive of his particular clique. Such an attack, however, were ignorance its only characteristic, would hardly call for remark. We notice it, not for its absurdity, but because, in combining with its absurdity a certain unctuous disingenuousness, it is really a typical example of a kind of criticism unhappily influential, if obscure, and widely accepted, if not popular. It would perhaps be too much to expect that reviewers of this class should read through the books they review, but at least they have no right to misquote what they do read. On p. 256 (first edition), Sir John Lubbock, speaking of errors into which, in the absence of education, not even Christianity prevented mankind from falling, writes thus: "We know that a belief in witchcraft was all but universal until recently even in our own country. This dark superstition has indeed flourished for centuries in Christian countries, and has only been expelled at length by the light of science." He then proceeds to observe: "The immense service which science has *thus* rendered to the cause of religion and humanity, has not hitherto received the recognition which it deserved." His reviewer, omitting any reference to witchcraft, quotes Sir John as asserting that "the immense service which Science has rendered to the cause of religion and humanity, has not hitherto received the recognition it deserves"—a proposition which may or may not be accurate, but is certainly not the one laid down by Sir John Lubbock. But he is not content with merely misrepresenting the book under review. Sir John Lubbock, he correctly remarks, at Liverpool, "frankly avowed 'there was no opposition between science and religion,' an admission," he adds, "of no slight importance by so great an authority in the scientific world, *as it is such a quiet rebuff to the boast of Bishop Colenso, that the differences between these two are such as to render it hopeless to attempt their reconciliation.*" If, however, we are bewildered at the brisk audacity which could venture on such a statement without even a hint at its wholly fabulous character, what are we to say to a critic who gravely asserts that "the Drift age had not been invented at the time" when Sir Charles Lyell wrote his "Geological Evidence of the Antiquity of Man"? and who assigns to the "prehistoric period in Sweden a minimum antiquity of 20,000, or it may be of 20,000,000 years."

But enough of the *Christian Advocate.* Turn we now to other and nobler opponents. The conclusions maintained by Sir J. Lubbock in this work are, in his own words—

"That existing savages are not the descendants of civilised ancestors.

"That the primitive condition of man was one of utter barbarism.

"That from this condition, several races have independently raised themselves."

On the other hand, we have the opinion of the late Archbishop Whately, that "We have no reason to suppose that any community ever did or ever can emerge, unassisted by external helps, from a state of utter barbarism into anything that can be called civilisation;" and that of the Duke of Argyll, who holds that the primitive condition of man was one of civilisation; that "there is no necessary connection between a state of mere childhood in respect to knowledge and a state of utter barbarism," and that man "even in his most civilised condition, is capable of degradation; that his knowledge may decay, and that his religion may be lost."

That the general propositions laid down by Archbishop Whately and the Duke of Argyll contain a certain limited amount of substantial truth, will probably be admitted by the staunchest adherents of the opposite theory. That "external helps" of some kind or other have played a most important part in the case of all civilisations the history of which is accessible, is as little open to question as the fact that under certain conditions civilisation among certain races may be arrested or may even retrograde. At the very threshold, however, of any discussion in terms less general, we are met by the question "What is civilisation?" The baffling complexity, indeed, of the idea conveyed in the word "civilisation" is the fountain-head of most of the confusion which exists among writers on the subject. That development is the vital principle, so to speak, of civilisation is universally admitted, but there would probably be a very general disagreement of opinion as to the particular kinds and directions of development which constitute the essential elements of civilisation. As generally understood, civilisation appears to involve a development more or less advanced of commerce and the means of communication, of natural advantages, products, and wealth, of navigation and warfare, of the arts, mechanical and ornamental; of science, theoretical and practical; of legislation and the administration of the law; of customs and language; of morals and religion; of all the faculties of the individual and the race. It includes also a consideration of the diffusion of personal liberty, and of the proportion of those who participate in the general welfare and possess the necessary appliances both for physical comfort and intellectual culture.

This, of course, is an inadequate definition of civilisation; and it is further manifest not only that development in many of the directions indicated is not absolutely necessary to civilisation, but that no civilisation on record has been equally developed in every direction. What is still wanting is some standard by which to measure civilisation in any particular case. Mr. Wallace, following Montaigne, appears to consider civilisation compatible with a very low development in nearly every direction. Archbishop Whately would consider as civilised the Germans described by Tacitus. The Duke of Argyll goes further still, for he seems to consider that Adam and Eve when expelled from Paradise were, nevertheless, distinctly civilised beings. The diversity of opinion is, indeed, owing to the absence of a recognised standard, almost universal. Civilisation is nearly always measured by the recorded achievements of men of genius. Yet, if this were the true test, no nation of modern Europe is so highly civilised as was Greece in the age of Pericles, and English civilisation has been retrograding from the days of Elizabeth, nay, from those which gave us the Canterbury Tales and Lincoln Minster, if not from those of Anselm and the Norman Bastard. Another fruitful cause of error is the natural but illogical assumption of the superiority of our modern Western European civilisation over all other civilisation. That in certain respects, principally material, it is actually superior, we do not of course deny, but when we contemplate the condition of our criminal, our pauper, our agricultural population, the troglodytes of the city, and the nomads of the country, it is difficult to avoid the conclusion that other civilisations, less advanced in certain respects, were more advanced in others, perhaps in some cases to an extent which turns the balance in their favour. On the whole, therefore, we apprehend that the relative civilisation of any country must be estimated rather by the sum of its general development than by its development, however advanced, in any particular direction. And this leads us naturally to a standard which, wherever it can be applied, is an infallible indication of the general civilisation of any race. General civilisation involves the multiplication of ideas, and the multiplication of ideas involves the multiplication of the symbols which express them. The language, therefore, or more strictly speaking, the vocabulary of any race, becomes a crucial test of its development. The total disappearance of numberless languages and our necessarily limited acquaintance with those which survive, obviously diminish, not only the number of cases in which this test can be applied, but the certainty of its application in particular instances. In spite of these drawbacks, however, language still supplies material to the student of comparative civilisation, not less invaluable than the material supplied by geology to the student of comparative anatomy. The imperfection of the record in both cases is extreme, but in both cases, so far as it extends, it is authentic and decisive.

We now return to the controversy between Sir J. Lubbock and his opponents. Independent of the cogent arguments adduced by Sir J. Lubbock against the conclusions arrived at by Archbishop Whately, there is one which seems to have been altogether overlooked. The Archbishop's theory traces the history of mankind up to a single primeval pair, and assumes the impossibility of their survival after their expulsion from the Garden of Eden unassisted by some supernatural revelation. Some supernatural revelation of the same kind he also holds necessary in order to raise any race to that stage of culture at which it is enabled to make progress of itself. The perfectly gratuitous character of this hypothesis seems to us its sufficient refutation. Surely it is sufficient to believe that causes analogous to those which, in later ages, gave to the world the exceptional intellects of an Aristotle or a Newton, possessed potency enough at an earlier epoch to account for the appearance of men endowed with genius to make the successive inventions recorded, without resorting to a superfluous hypothesis of supernatural intervention.

Even the Duke of Argyll virtually abandons Whately's position, although, perhaps, his own is even less logically tenable. When he tells us that there is no necessary connection between a state of mere childhood in respect to knowledge and a state of utter barbarism, we are forcibly reminded of Mr. Phœbus's eulogy on the aristocracy of this country, whose strongest points he declares to be that they live in the open air and speak only one language. It is manifest that the Duke of Argyll when he penned this passage had in his mind's eye the ideal "noble savage," who has figured so picturesquely in works of historic fiction from the days of Anacharsis downwards—a being who, although represented as in "a state of mere childhood in respect to knowledge," meets the greatest of civilised monarchs as his inferior, and convicts of folly the acutest of civilised philosophers. Unhappily this charming ideal person eludes the search of authentic travellers. They tell us of savages whose presence and bearing stamp them as gentlemen, they record many keen and pregnant sayings of barbaric wisdom; but the possession of the capacity for civilisation thus manifested is a very different thing from the possession of civilisation. Manly courtesy, strong commons ense, many of the moral virtues, are as compatible with a state of barbarism, as the absence of all these qualities is compatible with a state of highly-advanced civilisation. On the other hand, civilisation necessarily implies a familiarity with certain ideas to which "a state of mere childhood in respect to knowledge" is equally of necessity an utter stranger. In fact, both Archbishop Whately and the Duke of Argyll seem to have been the victims of a wholly imaginary necessity. They appear to have forgotten the syllogism implied in the old rhyme,

When Adam delved and Eve span,
Who was then the gentleman?

and have felt themselves under an obligation of crediting our first parents with a degree of civilisation utterly at variance with any accepted record of their condition. As Sir J. Lubbock observes, "Adam is represented to us in Genesis not only as naked and subsequently as clothed with leaves, but as unable to resist the most trivial temptation, and as entertaining very gross and anthropomorphic conceptions of the Deity. In fact, in all three characteristics—in his mode of life, in his moral condition, and in his intellectual conceptions—Adam was a typical savage" (p. 409, note). It may be added, too, that Adam's naming the beasts and birds is by no means incompatible with his otherwise barbaric condition. "It is remarkable," says Sir J. Lubbock, "that, supporting such a view, the Duke should regard himself as a champion of orthodoxy."

With regard to the question of degradation, however, the Duke has a slightly stronger case, though he has hardly made the most of it. That decline as well as progress in civilisation does really go on in the world is a historic fact beyond dispute. Egypt and Assyria, Greece and Rome, Mexico and Peru, groan with the monuments of ruined civilisation, and all history bears witness to periods of stagnation and decadence following on periods of progress and development. Nor is evidence wanting of an analogous sequence of events among the lower races. Degeneration is known in some instances to have taken place as the result of crossing ill-matched breeds; in others as the result of conquest, when the conquering tribe is in any respect less civilised than the conquered; in others, owing to the oppression of other tribes; in others, by the expulsion of a tribe into less favoured territories; in others, by a change in the external conditions of life,—in short, the whole of our present knowledge and experience tends to show that in every stage of civilisation from the lowest to the highest, development may be and frequently is succeeded by decline of greater or less duration and degree. So far we quite agree with the Duke of Argyll; and although Sir J. Lubbock admits the fact of occasional degradation, he hardly seems to us to recognise its real frequency and extent. In fact, however, it is only less universal than progress. For just as the present population of the world represents the difference between all preceding births and deaths, so the existing civilisations of the world represent the difference between all foregoing developments and declensions in civilisation. In other words, the present civilisation of the world bears witness to a vast mortality among previous civilisations, much in the same way as the present population bears witness to a vast mortality among previous populations. This consideration, however, so far from being favourable to the gloomy views of the Duke of Argyll, tells, on the whole, manifestly in favour of Sir J. Lubbock's more hopeful theory, for the tendency of civilisation like that of population, is always to increase and multiply. In both cases certain conditions may and do counteract the tendency in certain times and places, but the tendency remains the same, and sooner or later always predominates on the whole. It thus happens that all the great civilisations of the world have been in some material respect in advance of any which preceded them, and at the same time have manifested development in a greater number of directions. Thus the civilisation of Greece is more complex and more advanced than that of Egypt, that of Rome than that of Greece, that of Elizabethan England than that of Rome, that of modern England than that of Elizabethan England. It is to be observed, however, that every civilisation has some special and distinctive glory of its own unsurpassed by any of the subsequent ones. Grecian art, for instance, of certain kinds has never since been equalled, but the student of the Roman rule and law will certainly not be disposed to rank Grecian civilisation as a whole so high as the Latin. In fact, loss of some kind accompanies every gain of civilisation. One savage possesses the eye of the vulture, a second the scent of the deer-hound, a third the fleetness of the stag—civilise these men, and you destroy their special characteristics of excellence. Nor is this true only of physical qualities. Civilised man knows nothing of that barbaric power of perception and memory which enables the savage to detect at once the loss of one sheep out of three hundred, though he cannot even calculate the number of his fingers. Such losses, however, are in the long run more than compensated by gains in other directions, just as the losses incurred by the decay of one civilisation are eventually more than compensated by the benefits conferred by another. We fully agree, therefore, with Sir J. Lubbock in his remark at the conclusion of his answer to the Duke, "that the past history of man, has, on the whole, been one of progress, and that in looking forward to the future, we are justified in doing so with confidence and with hope."

But we have hitherto said nothing about Sir J. Lubbock's book itself. When we remember that it is one of the first attempts to treat the Origin of Civilisation on a rational and philosophic basis, we are not disposed to quarrel greatly with its somewhat lax arrangement. Its necessarily miscellaneous character lends it no small part of its value, and renders it exceedingly readable, but a more rigorous method and proportion are required to render it easy of complete digestion. In his laudable anxiety, too, to collect and co-ordinate facts as the only trustworthy foundation of his hypothesis, Sir J. Lubbock himself has a provoking way of latitating for a whole chapter together behind a heap of quotations, just when we want him to tell us their precise significance in that particular connection. This, indeed, and a very general absence of dates, deprives many of his facts of some portion at least of their intrinsic value. Occasionally, too, we come across a statement which we want verified, as, for instance, at p. 283, where he tells us "it is said that among the Ancient Britons money was habitually lent on what may strictly be called 'post-obits,' promises, to pay in another world." We own that we should like to see the authority for the prevalence of so singular a commercial transaction among our grandfathers. So far as we know, the Bonzes of Japan, and not the early Britons are the real culprits. A letter from a Jesuit father in Japan, dated March 1565, printed in Maffei's collection (B. iv. 2), tells how certain Bonzes were in the habit of borrowing money to be repaid with interest in another life, and giving their creditors I. O. U.'s (syngraphas) for *post mortem* presentation.

After all, however, Sir J. Lubbock's work is the completest summary of barbaric life that we possess. It does not profess to be exhaustive. It is designed rather as a breaking of the ground for further research in a direction precisely opposite to the "high *priori* road," on which theorists about the origin of civilisation have walked so long towards nowhere, discoursing prettily about the family being the first of human institutions, language being the perfect instrument of primeval thought, and so forth. In this respect, as well as in being a handbook of facts nowhere else collected together, it is undoubtedly a most useful contribution to contemporary literature. Its main value, however, consists in what we have only lately found a word for,—its "suggestiveness." Very few, even of the "cultured classes," at all realise the profound and abject barbarism of primeval antiquity. We can only guess darkly at the life of those wild ancestors of our race who fashioned and wielded the flint tools of the drift while yet the Thames was tributary to the Rhine,—how they skurried to their caves or burrows from the wolf, the bear, and the tiger, kept watch on the rhinoceros snorting in the shallows, or trembled as the mammoth herds crashed through the jungle. What were the relations among them of man to man, of man to woman? Was the one generally either the slayer or the victim,—the other either the temporary slave of an animal lust or the material of a fireless feast? Had they language beyond the scream of terror or pain, the shriek of triumph, the chattering of menace, the muttered mumbling of gratified gluttony? Who can tell? We know only that between the lowest savages of to-day and their earliest ancestors lies an interval of years far beyond the limit of historic chronology; and carefully weighing the facts of the case, we find it on the whole one degree less inconceivable and incredible that they should have risen to their present level of utter barbarism from one still lower, than that they should be the degraded progeny of any known or unknown civilisation.

SEBASTIAN EVANS

OUR BOOK SHELF

A Sketch of the Life and Writings of Robert Knox, the Anatomist. By his pupil and colleague, Henry Lonsdale. (London: Macmillan and Co., 1870).

DR. KNOX was in many ways a remarkable man, and if his life had been written with greater clearness of statement and less redundance of language, it might have been made both interesting and instructive. But those who have read Dr. Lonsdale's life of Professor Goodsir will not be disappointed by the present volume.

Robert Knox was born in 1791, and his misfortunes began by an attack of small-pox which destroyed his left eye. He was educated at the High School of Edinburgh, and became a student of medicine in the University when nineteen years old. Five years later he was appointed assistant-surgeon in the army, and spent more than three years on duty in the Cape Colony, where he seems to have made his first studies in ethnology and natural history. He next studied at Paris, and after his return to Edinburgh in 1822, became curator of the Museum of the College of Surgeons. In 1825 he joined Dr. Barclay in his extra-academical lectures on anatomy, and at once took the highest position in Edinburgh as a lecturer. He had many distinguished pupils—Goodsir, Reid, Edward Forbes, Owen, and Falconer were among them—and he appears to have been as popular with the students as he was disliked by most of his colleagues. In the winter of 1828-9 the terrible discovery was made of the system of murder carried on by Burke and Hare; and one of their victims was traced to Knox's dissecting room. This exposed him to much opprobrium, and even to personal danger from the Edinburgh mob; but his reputation was fully cleared from any suspicion of complicity in these crimes by the report of a committee of inquiry on the subject, which Dr. Lonsdale prints at length, together with a moderate and manly letter written by Knox himself to the *Caledonian Mercury*. That this affair was not the real cause of his leaving Edinburgh is admitted by his biographer, and amid the chronological confusion of the whole book the reader is left to guess the causes which reduced a class of five hundred in 1832 to nothing in 1842. Knox had been a candidate for the University Chair of Pathology in 1837, and for that of Physiology four years later. He failed each time, and the letters in which he submitted his claims give abundant reason for the enmities with which he surrounded himself. The latter of these productions, full of personal abuse of eminent men, some of whom are still living, was discreditable to Knox at the time, and its publication in this volume is still more so. We are told that "regardless of both legal and moral obligations, he commenced lecturing on anatomy in Edinburgh in 1842, but got no class." He tried lecturing at Glasgow, failed again, and after various wanderings settled in London. Here he maintained himself as a popular lecturer and a literary hack. Among his other occupations during the last melancholy twenty years of his life, he was pathologist to the Cancer Hospital, he contributed to the Proceedings of the Anthropological Society, and he practised midwifery. Hard working to the last, he died in London at the age of seventy-one.

The moral of this life seems to be a very trite one; Knox was his own enemy. In spite of a biographer's adulation, we are told that "on matters of business involving a *bonâ fide* principle, Knox was prone to be evasive, whilst on matters of fact he was not always considered trustworthy."* Yet he must have had redeeming qualities, and made warm friends as well as bitter enemies. As an anatomist, he belonged to the older British school, and possessed many of its merits. He did good work on the *Cetacea* and *Sirenia*, and appears to have been the first to maintain the true nature of the ciliary muscle, as well as to describe the *fovea centralis* in the retina of reptiles, and the tracheal pouch of the emeu. He was also a leader in the study of ethnology as

* This statement is introduced by the remark that "a portrait of the anatomist, without its shadows and sinuous lines, would be no portrait at all." No doubt there were many such portraits of Knox on the blank walls of Edinburgh, when he was abused as the accomplice of Burke and Hare; but Dr. Lonsdale has done wisely in giving his readers the characteristic sketch of the anatomist lecturing, which was taken by his brilliant pupil, Edward Forbes. This sketch is the best thing in the book.

a branch of anatomy. But his great distinction was as a lecturer, and here his success was for a time unequalled. Like other teachers of the time, he had the advantage of introducing a great deal of comparative anatomy, physiology, and histology (so far as it was then known) into his lectures on human anatomy. He must have been gifted with great natural eloquence, and disdained none of the tricks of oratory. His biographer gives a wonderful account of the clothes he wore when lecturing, in what seems to have passed for "full dress" in Edinburgh about 1830, but also informs us that "the richest costume would hardly have availed had not the silvery tongue been brought into play." Knox never drew diagrams, and equally rejected the help of ready-made drawings for his class, nor did he ever use notes. Above all, he thoroughly enjoyed his work. He left little written that is likely to preserve his fame. His translation of Milne-Edwards' "Zoology," by which he is perhaps most widely known at present, is a bad specimen of his inferior work. The history of his life, besides its interest as the record of an able man's remarkable success and as remarkable failure, is of importance from the light it throws on the study of anatomy in this country, on Scottish university politics, and on methods of scientific teaching; so that the intention of the present work is more praiseworthy than its execution. P. S.

Strange Dwellings: being a Description of the Habitations of Animals. By the Rev. J. G. Wood, M.A., F.L.S. (Longmans & Co., 1871.)

MR. WOOD'S works are well and favourably known as presenting the study of Natural History in its most attractive form to the young. The present work is not new, being abridged from his "Homes without Hands," which obtained, some years ago, a deservedly large amount of popular favour; and even in its original form it consisted of course mainly of selections from accounts given by travellers and naturalists. It is, however, extremely well suited to place in the hands of any boy or girl who is already fond of reading about strange animals, or whom it is desired to interest in the study of nature. We find in it accounts of the curious trap-door spider of Jamaica, the bower-bird of Australia, with its remarkable edifice of twigs and shells, the mud wasps of Guiana, the repulsive-looking aard vark of South Africa, the weaver bird and tailor bird, and many other animals of singular habits, and illustrated with woodcuts, which combine with the lively style of the text to make the volume a very attractive one.

The Duke of Edinburgh in Ceylon: a book of Elephant and Elk Sport. By John Capper, *Times* correspondent. Illustrated with chromo-lithographs. (London: Provost & Co., 1871.)

THIS book is sufficiently described by its title, being a record of the visit of the Duke of Edinburgh to Ceylon last year, and of his success in the colonial sports of elephant hunting and elk hunting. It appeals to two sections of the public, those who eagerly seize upon every incident connected with the mode of life of any member of our Royal family, and those who are equally eager after any description from life of sport in those countries where wild beasts worthy of a hunter's rifle abound. We may quote the following as an instance of the perils encountered by our Prince in navigating the Cingalese rivers. "The stream was teeming with life. Fish of all varieties and sizes sprang into the boats as they paddled along, one of them finding its way into the Prince's coat pocket" (loyal fish!); "on all sides could be heard the snapping of alligators' jaws as tiny fish were caught in the monsters' mouths. The party had proceeded about a mile down the stream, when one of them, leaning down and resting his head on the gunwale of the boat, was startled from his quiet rest by the apparition of an alligator's gaping jaws, which made a direct snap at his head, fortunately missing it, but seizing, in place of it, the barrel of the rifle held in the hands of the Prince's English attendant, who was seated next to him, and which the monster nearly wrenched out of his hand, splashing the water about, and drenching every one in the canoe." Is the *Times* correspondent quite certain that alligators are found in Ceylon?

Lunar Halo seen from Two Stations

I HAVE presented to the French Institute at its last sitting a copy of NATURE, January 26, with the sketches of a halo seen from Liverpool by two different observers from two stations at a little distance. It is the first time, as far as my knowledge goes, that we have had two different sketches of the same phenomenon. The difference is very considerable indeed, as a *paraselene* was seen by one of the observers, and not by the other. It would be very important to ascertain what was the exact situation of each of them, and I should be glad if you can take the trouble to ascertain it by an inquiry through your paper. When I return to England I will ascertain the circumstances of the observation, which may lead to some definite conclusions on the form and altitude of floating snow during the night of the 4th January.

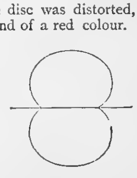
In my note to the French Institute, I say that, unquestionably, reflexion or refraction took place on several faces of crystalline snow, and each observer saw the refraction or reflexion on a particular face of crystal, placed conveniently for observation. So that double observation is very valuable, as affording a direct proof of the correctness of the explanations given by Mariotte, and others after him, of these magnificent appearances.

According to Mariotte's theory, the presence of a paraselene in one of the observations with the halo of 22° shows the presence of prismatic crystals, the faces of which must be hexagonal. The second appearance should, according to my opinion, show that these crystals were terminated by small pyramids, and the other observer perceived the halo reflected on the oblique face of these crystals. As he saw two or three halos almost concentrical, it must be supposed that one of them was due to the upper pyramid and the other to the lower.

Very probably the air was not disturbed by any wind, and elongated crystals were falling very slowly, or rather floating, owing to the smallness of their dimensions, which possibly may have been a small fraction of $\frac{1}{100}$ inch.

I send you these suggestions only to direct further inquiries, and I make no pretension to exhaust the subject, which is very interesting.

I myself observed on Thursday, February 12, what is not quite unworthy to be noticed, as showing how inexhaustible is the field opened by Nature to her inquirers. The sun was setting when I arrived at St. Pierre le Calais with my friend Alexandre Lille. I noticed the disc was distorted, the two partial suns being almost alike, and of a red colour. This appearance was



certainly owing to the air not being of a uniform density. Two different streams were separated by a horizontal surface. The truth of this supposition was very easily ascertained, as two different kinds of clouds were flying in two different directions. Neither of them was heavy, and the distinction was very admirably made by the sun itself, which soon disappeared, leaving a rosy tint behind him. The lower clouds first presented a rosy colour, but soon became dark, and the upper clouds in their turn took the beautiful colour which the others below were just losing. The horizontability of the surface separating the two streams of air was a proof of great quietness in the atmosphere, and the night was magnificent, as well as the following day.

W. DE FONVIELLE

Quinary Music

MR. JEVONS, in his interesting paper on the Limits of Numerical Discrimination (NATURE, Feb. 9), asserts in support of his views (Rees Cyc. "Rhythm") that "no musicians have yet been found capable of performing" quinary music.

I have never found the slightest difficulty, nor can I conceive any, either in performing or inventing music subdivided into five isochronous measures, *i.e.*, with an accent recurring on every fifth unit of measure; nor do I see anything to justify his doubt that the ear can grasp divisions of 6, 8, 9, without regrouping them into smaller periods; as amongst skilled musicians there exists no doubt whatever about the continuous reading of those larger groups, without even a suggestion of such subdivision; and it would be easy to multiply quotations from the best writers of passages whose only correct performance *and reception by the listeners* would be entirely destroyed by such a sub-grouping as Mr. Jevons seems to think necessary.

Apropos:—I greatly doubt whether the question of musical time is at all pertinent to the subject of numerical discrimination, as an instantaneous conception; the latter being a synchronous mental act, while the former is altogether consecutive in its operation, in which every group, however small, is only a sequence of units. JOSEPH MULLEN

38, Synge Street, Dublin, Feb. 14

The Power of Numerical Discrimination

IN an article with this title in a recent number of NATURE, Mr. W. S. Jevons offered the results of some ingenious experiments he had been making to determine how many objects the human mind could count by an instantaneous and apparently single act of attention. He comes to the conclusion, that the power of his mind was limited to something less than five.

If it were Prof. Jevons' purpose to ascertain the number of objects he could count within an interval too short for more than a single conscious act of attention, his experiments were, doubtless, conclusive, at least to him; but if he sought through them to prove that he or any other person could fix his attention upon more than one object at a time, I fancy he commits the mistake attributed to the Royal Society in puzzling over the question put them by Charles I. about the effect of throwing a shrimp into a pail full of water. He is trying to account for a phenomenon that never occurred and which can never occur.

Prof. Dugald Stewart, in his work on the "Philosophy of the Human Mind"* has proved very clearly, it seems to me, that the attention is never fixed upon two points or objects at the same time, but that it passes from one to another in certain cases, as in playing upon musical instruments, in feats of jugglery, &c., so rapidly as to seem to be instantaneous.

In addition to what Prof. Stewart has said upon this subject, permit me to ask how it is any more possible for the attention to be fixed on two beans at one time than for two beans to be in the same place at the same time? The argument that could demonstrate the absurdity of the last of these propositions would demonstrate the absurdity of the first.

If Mr. Jevons will try to look at both eyes at once of the first person he talks with, he will find that one of the eyes seems more distinct to him than the other, and every effort he may make to equilibriate his attention will only result in changing it from one to the other.

If he is talking with great earnestness, or in a way to make his interlocutor very anxious to divine his meaning and penetrate or anticipate the expression of his inner thoughts, he will notice that his interlocutor's eyes seem to be running from one of his own eyes to the other, as if in hopes of getting from one some disclosures not made by the other. This would not be done if both eyes could be seen simultaneously.

Mr. Jevons seemed to see five beans, because he was able to run over and count five in the minimum of conscious time.

I think there is no authority for saying that there is any period of conscious time necessary for any purely mental operation. To the mind itself, or the spirit of a man, there is neither space nor time. There are incidents of our material organisation which limit our capacity to notice and remember mental operations, but not the operations themselves. Therefore the rapidity with which the attention is transferred from one word to another in reading, or from one key to another of a piano when played by a master, authorises no presumption whatever that his attention is ever fixed upon more than one key at a time, while all the presumptions are against the possibility of any person's attention ever being in two places at the same moment. Eozoön Canadense

ON a careful consideration of Dr. Dawson's reply to the objections urged by me against the supposed organic nature of Eozoön Canadense, I confess my inability to see that one single fact is brought forward calculated to shake the position of those who regard it as a purely mineral production.

In opposition to all previously received opinion, Dr. Dawson would now confine Eozoön to the Laurentian period. I am glad to accept this as evidence that its Canadian discoverers begin to feel the force of the "difficulties" I have stated, and instead of ignoring them, make a genuine and *direct* attempt to meet them.

Though Dr. Hunt now doubts the accuracy of the observations which refer the Skye ophite to the Lias, he has elsewhere as good as admitted that it is not confined to the Laurentian period.* Gümbel has also determined it for Cambrian metamorphic rocks in the Fichtelgebirge, Bavaria, and Rupert Jones and Sandford for rocks of the Lower Silurian period in Connemara, as pointed out by Mr. Kinahan in his letter in NATURE (No. 66). The Tudor specimen, it is also considered, may belong to the Cambrian or Potsdam group. This, to say the least, is somewhat contradictory.

The determination of the age of the Skye ophite I am willing to leave Dr. Hunt to settle with Professors King and Rowney, merely remarking that both McCulloch and Geikie, as independent observers not looking for evidence in support of a theory, declare the rock to be of the Liassic age.

The lengthy disputes as to what is to be considered Eozoön and what is not, are most amusing. When each disputant takes up a different position and shifts it as occasion requires, how is he to be met? And is this not of itself sufficient *primâ facie* evidence of weakness such as to warrant a suspension of judgment on the part of those—and their number is great—who have accepted the "fossil" only on the strength of eminent names and reiterated assurances?

As far as I can make out, the whole positive evidence is now narrowed down to the determination of what is and what is not the true "nummuline layer." A reference to the published figures and descriptions gives no information by which we may detect any difference between the "nummuline layer" of the Skye ophite and that of the typical Canadian specimens. Thus, then, until Dr. Dawson points out the difference, this objection cannot be said to be "wholly irrelevant." To aver, without proof, that when the characteristic structure occurs in an unlooked-for position, that it is an *initiative form*, or, on the contrary, to assume it to be a *fossil* when discovered elsewhere, is easy, but does not tend to carry conviction to the unbiassed mind. To do this, we require distinct and ample evidence. The Eozoön before referred to as discovered by Mr. Sandford in the Connemara ophite, and "verified" by Rupert Jones,† belongs, according to Murchison, to the Lower Silurian age.‡ The discovery, it appears, had at the time induced Sir Roderick to class this rock as Laurentian, but shortly afterwards, purely from stratigraphical considerations, he pronounced it to be Lower Silurian.§ Here, again, we have a discordance with the views of Dr. Dawson; are we, then, to throw away such independent testimony, and say that the unfortunate Eozoön "Hibernicum" is an *imitative* form, or, are we to consider the veteran geologist wrong, and the Connemara marble Laurentian?

It is now seen that all the theories which attempt to meet the objections I have stated are in conflict—which then is right?

As regards the Tudor specimen, which, it is thought, I have too summarily "disposed" of, I would observe that it was brought forward with great *éclat* as a conclusive answer to all objections founded on the comparison of the structures of Eozoön with the forms of fibrous, dendritic, or concretionary minerals. The reasons why I dissent from this view are: 1st. The "chambers" are admittedly "more continuous and wider in proportion to the septa" than specimens found elsewhere. They are, in fact, little more than an aggregation of concentric plates or perhaps only bands, and according to the figure do not show the true segments. 2nd. The microscope reveals "for the most part merely traces

* Silliman's *American Journal*, July 1870
† Geological Magazine, vol. ii. p. 87.
‡ Ibid. p. 147. § Ibid. p. 97.

of structure consisting of small parts of canals filled with the dark colouring matter of the limestone," and in only "a few rare instances" are detected "with a higher power in the margin of some of the septa traces of the fine tubulation characteristic of the chamber wall of Eozoön." 3rd. It is almost an isolated example, and the measure of the metamorphism of its matrix together with its character—organic or otherwise—(from its generally doubtful nature as shown by Dr. Dawson's own description) could only be ascertained and settled by independent inquiry.

I may also here observe that other cases of "chambers and canals stated to be injected with calcite appear to me to be of a no more reliable character. If, indeed, we accept the Tudor specimen and Madoe fragments as Eozoön, why refuse this term to the Skye specimens which apparently possess the true features (chamber casts and nummuline layer) in a much more marked manner? As regards imitative forms, Dr. Dawson and myself are in agreement, excepting that I must contend, from all the facts we are acquainted with, that *all* Eozoönal forms are imitative, and not merely those that the exigencies of the discussion demand looked at from the organic stand-point.

Respect for your space prevents me going into further details, but I may be permitted to suggest that the truth of the matter in no way hinges upon the possibility of comprehending the constructive pseudomorphic theories advanced by King and Rowney. In what way though, excepting by pseudomorphism, I would ask, does Dr. Dawson account for the presence of the *imitative forms* which he thinks have confused other observers? And if we believe pseudomorphism to have originated them, why is it so trying to our faith to consider Eozoön Canadense to have been formed in the same manner? The fact is, chemical geology and the replacement and alteration of minerals—occurring as they do in the forms of other minerals—have been little studied by palæontologists, or probably Eozoön might have remained "unconstructed" to this day. It is well known that not only do minerals assume by replacement the crystalline forms proper to the mineral replaced, but also amorphous shapes filled with one mineral may be replaced by another without in any way destroying the original form.

There can be no doubt that a little knowledge of this kind would have infused the necessary caution, and have prevented anyone accepting as a fossil that which required the invention of a method of chemical deposition (excepting in these pages) hitherto unknown in nature. Serpentinous marble, as we may ascertain from all sources, is the typical Eozoönal rock, and, though the minerals filling the so-called chambers and canals may be Loganite or pyroxene, in addition to the serpentine, they are intimately related in a pseudomorphic point of view. Loganite and serpentine, as I have before stated, are both products of alteration. The organic hypothesis demands that we should consider the infilling to be, as contended for by Dr. T. S. Hunt, the *same mineral originally supposed to be deposited therein.* If this be so, then what becomes of the meaning of metamorphism? This to me is a trial of faith greater even than the acceptance of King and Rowney's "constructive criticisms."

I await with interest the publication of the papers sent to the Royal Irish Academy by Dr. Dawson and his colleague, Dr. Hunt, and trust they may contain new matter for consideration, as my only object has been to elicit further evidence, if there be any, in favour of the organic hypothesis.

Feb. 17 T. MELLARD READE

Ocean Currents

IN reference to Mr. Laughton's letter in NATURE of the 23rd of February, I must admit that the question of the movement of barometric depressions was not introduced into my first letter, for the reason that I did not anticipate the objection of a state of equilibrium which he raised, since the average differences of pressure only were dealt with; but I do not see that it necessitates a change of ground to show how this difficulty is met by the variations which occur in the region of lower average pressure, and how these changes themselves, taking place in a certain line of movement, might affect the surface currents of the ocean; and I am not disposed to accept the sweeping rejection of the whole power of differences in the atmospheric pressure, permanent or moving, which is contained in the last paragraph of the letter referred to, until more extended observations shall show what directions the great movements of changing pressure take in passing over the parts of the ocean which lie outside of the trade wind regions.

The action of a barometric depression in moving over the sea differs entirely from that of the winds in this, that by the former the level of a large area of the ocean surface may be raised and carried along with the depression round which the winds blow, whilst by the force of the latter the waters can only be drifted at the same level before the wind.

I have been particularly careful to suggest difference of atmospheric pressure only as a supplementary power in the production of ocean streams, not as a chief one, and it was indeed the partiality of the various theories of the causes of currents which led me to open the subject at all.

That the trade winds have a very large share in originating the Gulf Stream is undoubted, but that they can account for the whole of the phenomena of ocean currents, as Mr. Laughton maintains, appears more than doubtful.

The existence of the under outflowing current of the Mediterranean, corresponding to the inflowing surface stream, has been abundantly proved by the recent Government expedition under Dr. Carpenter. If this current be due to the action of the winds alone we should expect to find the direction of the upper and under streams reversed with a change of wind to opposite points east or west in the Strait. But the observations on the direction of the winds for six years at Gibraltar show that westerly winds (from N.W., W. and S.W.) prevail there for 198 days in the year, and easterly winds (N.E., E., and S.E.) for 144 days; further it happens that in the months of July, August, and September, in one of which the observations on the outflowing undercurrent were made, east winds prevail in the ratio of two days to one day of west wind. Experiments similar to that used to determine the presence of an under-current in the Strait of Gibraltar, have been made in the open ocean, and Maury (at p. 206 of the 9th edition of his work) quotes an instance of an apparatus constructed of a block of wood, sunk by weights to 500 fathoms, and attached by a line to a small floating barrel, having moved off "against wind and sea, and surface current." The members of the late German Arctic expeditions have observed that where the warmer blue waters moving from south-westward meet the impure waters of the Spitzbergen and east Greenland current, there is a definite line of demarcation which would indicate that the Atlantic water here dips down beneath the specifically lighter water of the ice-bearing current, a conclusion which is supported by the increase of temperature with the depth beyond this point.

Such under-currents can in no way be primarily caused by the action of the winds, and if difference of temperature and density must be called in to account for them, it must be admitted that these causes have to do with the upper streams also.

I would take this opportunity to correct a statement made in my second letter, of a probable movement of a barometric depression across the British Isles at the rate of ninety miles an hour. The depression there referred to appears to have had an oblong form, the longer axis moving nearly parallel to the length of the British Isles from N. to S., so that the record of its passage took place at Valentia and at Aberdeen within a short interval of time, thus giving an apparently great rate of travelling. But I have the authority of the Secretary of the Meteorological Office for the facts given beneath, which prove that a rate of depression movement of upwards of seventy English miles an hour may take place. On the 16th of December, 1870, a minimum reading of the barometer was registered at Valentia at $2^{h}\ 45^{m}$ P.M.; at Kew, at $9^{h}\ 30^{m}$ P.M.; at Yarmouth, at 10^{h} P.M., where the mercury remained at the same level for four hours. The interval of time between the registrations at Valentia and Yarmouth is $7^{h}\ 15^{m}$; the distance between these places is 520 miles. It seems probable also that the centre of the depression moved directly from Cork to Yarmouth, for the wind records prove that it passed north of Falmouth, and south of Holyhead and of Valentia.

KEITH JOHNSTON, JUN.

Perpetual Motion

PROBABLY your sense of justice will induce you to insert some very brief remarks on your review of my article in the *Quarterly Journal of Science*. The tone of the review is a penalty which all who venture to impugn commonly accepted theories must be prepared to submit to. Heresy in science meets with as little mercy as heresy in theology. I confess that in one sense of the word I am consciously a perpetual-motionist, but not in the sense of believing that any merely mechanical contrivance can produce perpetual motion. That there are forces in nature which can and do produce it, is a matter of daily, yearly, and secular experience. If I am a perpetual-motionist in this sense, I am in good company. You will find that Sir W. Thomson, in the *Philosophical Magazine* for February 1854, described a machine by which a steam-engine or water-wheel could produce thirty-five times the heat commonly considered as equivalent to the force used; or the corresponding amount of cold. At that time, then, two years after his paper read to the British Association (to which you refer me), he certainly did not hold such an opinion with regard to the mechanical equivalent of heat as to exclude the possibility of such an engine.

The final judgment of the question I confidently leave to time and facts. When any of the "grand founders of a rapidly progressive science" can spare time from their investigations to refute my fallacies, I shall gladly retract them. H. HIGHTON

The Spectrum of the Aurora

IN the sketch appended to my letter on this subject in last week's NATURE, I notice that the engraver has made the line at 4·1 much too sharp and definite in both spectra. It really shades off rapidly to the more refrangible side, at least in the spectrum of the vacuum tube, and possibly also in that of the aurora. Though much the brightest line in the auroral spectrum, it is not the most conspicuous in that of the tube, but the relative brightness of lines frequently varies much at different temperatures. The band at 8 in the auroral spectrum is also represented too narrow. Those who have practical experience with the spectroscope will appreciate the great difficulty of representing faint spectra correctly in a woodcut.

HENRY R. PROCTER

Science Teaching for the People

THE subject of Science Teaching in our elementary schools having been ably brought forward by Mr. Henry Ullyett in a recent number of your Journal, and the scientific instruction under the Science and Art Department, South Kensington, having been at various times the subject of consideration in it, I venture to ask for a short space in your columns in order to submit the following proposition for the consideration of your readers, many of whom, have, probably, special opportunities of coming to a correct judgment on the point. The question I wish solved is this: Is the spread of scientific education, under the auspices of the Science and Art Department, likely to be best promoted by the whole of the Department's assistance to any one town being dispensed by a single committee, by whom a central school shall be provided, of which all other schools established, or that may be established, in various districts of the town, shall be considered only as branches, and be subject to the control of the central committee, on whose books the names of all students would be borne, and through the one secretary of which all the returns and other communications to and from the Department would have to pass?

Is it not better that the schools established in various districts of a town, say in connection with each elementary school, should each have their separate organisation of committee and secretary, at least in so far as the teachers connected with each are different? In this town, in common with a great many others, the latter plan has been the rule, but a suggestion has now been made that all these committees should be amalgamated, together with those of the art-classes also, the plea being that it might lead to the erection of a central building for the purposes of an art and science school.

Now, however necessary for art it is that there should be a central building for the provision of higher instruction than can be given in the night classes, I cannot see that there is anything in the study of science that demands greater facilities than can easily be provided by any district school, and the possession of which is indeed required by the Science Directory before any science school receives the approval of the Department.

Why, then, the science committees should be asked to unite in this town alone, by which a most dangerous precedent would be established, I cannot understand, for I do not believe that such a course would be beneficial to the town at large, while it would be very prejudicial to the interests of the existing district schools, and of any persons wishing to commence teaching in future.

Perhaps some of your readers will favour us with their views on the question I have stated, which I venture to think involves a principle of very general interest to the science schools of the kingdom. A MEMBER OF A SCIENCE COMMITTEE

A Rare Moth

IT may be interesting to know that the rare and beautiful moth, *Deilephila Galii*, appeared somewhat plentifully in the neighbourhood of Derby during the past summer. I have in my possession a fine male and female which were captured at Long Eaton, some few miles from Nottingham, whilst flying in company over a bed of geraniums. Is not this the first recorded instance of their appearance in this locality? *Zeuzera Æsculi* also appeared in unusual abundance in the same garden, upwards of fifty specimens being taken by one person. W. H. G.

Measurement of Mass

WILL you allow me a few words in explanation of a sentence in my last letter, which has strangely been misunderstood by Prof. Everett. In defending the system which makes the standard pound a unit of force on the ground that although not the most philosophical, it simplifies the conception of mass which is always difficult for beginners, I said, "The assumption of a hypothetical force of gravity not dependent on latitude, seems to stand on the same footing as the employment of a mean solar day," meaning, of course, that just as we assume (for convenience) that a solar day is the same length at whatever period of the year we take it, so we may assume a mean force of gravity (the actual force of gravity in latitude 45°) which is the same all over the earth. Such an assumption will enable us to explain the unfamiliar notion of mass by the familiar one of weight, and when it does become necessary to take into account the variation in the force of gravity at different points of the earth's surface, the correction is easily made.

Prof. Everett seems to think that I suppose that the average length of the apparent solar day is not the same at all places on the earth. Will you allow me to quote the following passage from the original in support of my first assertion, that Prof. Everett's tacit assumption that everybody knows what mass is, is less likely to lead to clear ideas than the explanation given by Deschanel. He says—"Un corps a une masse plus grande qu'un autre lorsque la même force lui imprime une vitesse plus petite, et reciproquement, ... si nous considérons en particulier le poids d'un corps, on aura, entre ce poids, la masse et l'accélération de la pesanteur, la relation fondamentale,

$$P = Mg$$

Cette formule nous montre que dans le même lieu le poids est proportionnel à la masse, parceque g a la même valeur pour tous les corps. Il n'en est pas de même quand on passe d'un lieu à un autre; mais comme après tout les variations sont extrêmement petites, en réalité la masse et le poids sont deux quantités toujours sensiblement dans le même rapport. Toutefois il faut se rappeler que ces deux expressions correspondent à des notions distinctes, et, abstraction faite de toute évaluation numérique, la masse d'un corps est quelque chose qui lui est propre et qui est indépendant du poids. La pesanteur n'existerait pas qu'il n'en serait pas moins vrai qu'une sphère de plomb a une masse plus grande qu'une sphère de liége de même diamètre. Nous reconnaissons ce fait ordinairement à ce que la poids de la première sphère est plus grande que celui de la seconde; mais à défaut de la pesanteur, l'emploi de toute autre force pourrait nous conduire au même resultat." W. M. W.

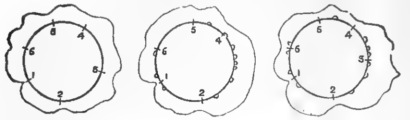
PHOTOGRAPHS OF THE ECLIPSE

PERMIT me to call your attention to the position of the woodcut illustrating my remarks on the Eclipse Photographs. The south point is where the north should be. As what I have now to say refers to the picture I shall feel obliged if you will permit its reinsertion in its true position.* With reference to the power of the light of the Corona, I used the word *actinic*, not *active* as printed.

The readers of NATURE may perhaps be glad of the opportunity to compare for themselves tracings of the American and of my own photographs, which I now give in outline in illustration of remarks in your second article

* This vexing mistake was due to a blunder of the printer in reversing the block after it had been placed on the machine. Its re-insertion this week will rectify the mistake.—ED.

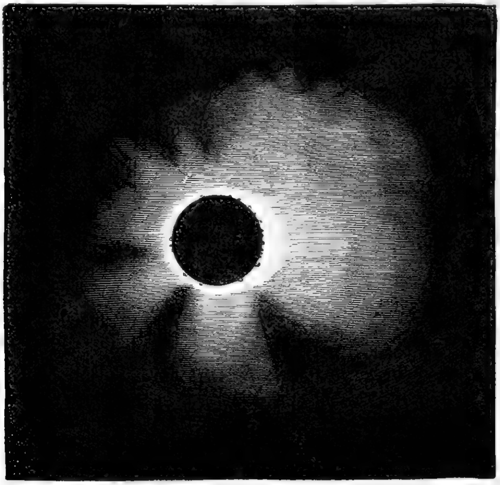
on the Eclipse Expedition. In Mr. Lockyer's article it is stated :—" Now at Syracuse Mr. Brothers also photographed rifts, three rifts, but the sketches did not record a single one ;" forgetting, evidently, that at Syracuse no



I — From Prof. Watson's Drawing. II — From American Photo. taken at Cadiz. III — From Photograph taken at Syracuse.

attempt was made to sketch the Corona either by our own party or the Americans. At Agosta Mr. Brett was stationed, but as the Eclipse was only visible there for about *five seconds*, of course in that time no artist could pretend to make a drawing. It happens, however, that Prof. Watson was at Carlentini, and being favoured with a clear sky he succeeded in making a very careful drawing, which I had the good fortune to see and compare with my photograph No. 5 a few days after the Eclipse. An outline of this drawing I now give, so that it may be compared with the photographs made in Spain and at Syracuse.

There are two or three points which must be considered in comparing drawings and photographs. The photographs will differ according as they are made with a camera or telescope, and the drawings will differ according as they are made with the aid of a telescope or without. With the telescope the field of view is limited, and the eye is naturally attracted chiefly by the intense light of the red prominences and the corona near the moon's limit. Naked-eye drawings ought to be as valuable as photographs, but I doubt if any two artists will ever be found to make sketches agreeing in every particular. On photography must we depend for settling doubtful points of this nature, and it seems to me in this case to be absolutely settled that three rifts are identical. The outline sketches speak



THE LATE ECLIPSE, AS PHOTOGRAPHED AT SYRACUSE

for themselves. A pair of compasses applied to the points formed by lines drawn from the moon's centre to the centres of the depressions (or rifts) in the corona, will show whether or not the places of the three gaps are the same.

It may be said that Lord Lindsay's photographs taken five miles from the station occupied by the American observers in Spain, do not show the rifts. This, I think, must be accounted for by the presence of cloud. The cloud may have been so thin as to be quite invisible in the feeble light of the Eclipse, but yet sufficient to prevent the photographic delineation of the rifts. Three of my photographs were taken through cloud, and they show us traces of rifts. The fifth plate shows three distinctly, and less plainly five or six others.

Professor Watson's drawing shows two gaps corresponding with 1 and 6 in both photographs, and depression in the corona agreeing very closely indeed with my picture.

This evidence seems to me to be absolutely irresistible as to the identity of the great rifts in the corona.

In explanation of the way the outline drawings have been made, I may say that the points marked from 1 to 6 have been pricked through the photographs, Professor Watson's drawing having been reduced to the same scale as the photographs, and pricked off in the same manner.

A. BROTHERS

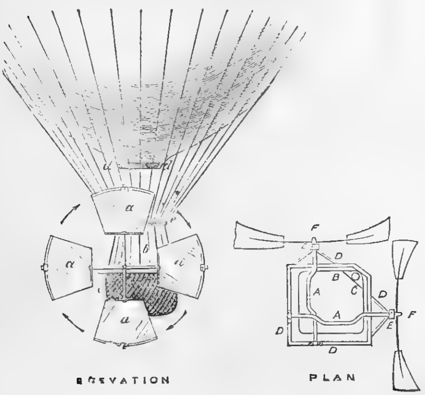
EXPEDITION OF THE "DUQUESNE"

M. RICHARD, master in the Royal Navy, directed the Expedition, and is now attached to the Lille aëronautic station for the Department of the North. I have interrogated him and elicited from him the following details, which can without inconvenience be placed before the eyes of the general public. The French Republican Government having in view the promotion of general knowledge, as well as the defence of the national integrity, did not object to any communication which is not directly connected with warfare.

The aërostat, "Le Duquesne," was despatched from Paris on January 9, at three o'clock in the morning, before a large attendance, among them some members of the French Institute. The reigning current was a strong S.W. wind, which was unfavourable for escaping the Prussian lines, as the intended directing power was only a motion of three feet per second. The experiment should have been postponed for a fair trial. Another drawback to the Expedition was the despatch of the balloon in the night-time, although the moon, being almost full at the time, afforded some light to the aërial travellers, being very low on the horizon when "Le Duquesne" left the Orleans railway station. There were in the car M. Richard and three sailors of the national navy, so that two could be kept pulling without interruption; three sacks of despatches, four pigeons, eight sacks of ballast, thirty kilogrammes each, were also in the car. The provisions were bread, wine, and chocolate. The weight of the machinery was 300 pounds. As will be seen by the accompanying diagram, the two screws were worked by a very simple contrivance, rotating only at a rate of twenty-five rotations per minute, but the diameter four yards, so that the motion in feet per second of the screws was about sixteen, five or six times more than the rapidity intended to be given to the balloon, which was three miles an hour.

Before leaving ground the car had been placed with its diagonal due north. But that precaution proved useless, as the balloon rotated when ascending before the screws could be put into operation.

We will give the explanation under M. Richard's own authority, with some remarks. We are certain of his perfect truthfulness, but it is very hard to say if he saw everything correctly for the whole length of the eventful journey.



THE DUQUESNE DIRECTING BALLOON, DESPATCHED FROM PARIS JANUARY 9, 1871

a a a a segments of the screw revolving in the direction of the arrow or the opposite direction, with variable rapidity; *b* valve line; *c* car; *d* appendage *e* hoop.

A A handle for moving screw, two men pulling at once; C place of the captain; B place of one man; D D board in iron tubes fixed to the car; E E extremities of the axes; F F fixing screw, which can be removed so that wheels may be thrown overboard when landing.

The observers on the ground had placed themselves in a right position to ascertain the effect of the screws, and the *compte-rendu* published in Paris gave the summary of their impressions. They suppose M. Richard succeeded in giving to his balloon a deviation of 15° from the due course of the wind during the earlier part of his journey. If experiments had been made during daylight, matters should have been more easy to ascertain. If I can procure authorisation, I will get an experiment tried anew at the Crystal Palace before an English audience. The fact is that two of the three sailors pulled with all their strength during a few minutes, after having exhibited some hesitation in the first instance. The scenery was so magnificent that it was necessary to call them twice before they began to pull.

M. Richard soon perceived that he was unable to ascertain the effect of the propeller. He resolved upon letting the balloon follow its way undisturbed, and he noted carefully the barometric altitude and the direction. When passing over Prussian lines at an altitude of $0^{mm}\cdot69$, some shots were directed at the balloon without any result.

At $3^h\ 10^m$ altitude 0·68° was reached; temperature 20° F. The Valley of the Marne was below.

M. Richard turned the screws and tried to pull towards the north, in order to go N.N.E; but the rotation was difficult to stop. It was necessary to work only one screw during a long time in order to rotate the aërostat in the right direction. It was only when some real torsion was established between aërostat and car that the required revolution took place. But when movement was given to the balloon it was difficult to prevent it, and the aërostat executed one entire revolution against the will of its captain. Then the two screws were worked together; the same effects were produced, but it was only with great difficulty that the car was placed in the right direction. When the two screws were worked together, the balloon was rotating sometimes in one way and sometimes in another. These observations, moreover, says M. Richard, were made at night by a man who had never before ascended in a balloon. As already said they cannot be considered as wholly reliable, as rotation depends on the changing of the fuel as well as on the friction in the forward half or on inequality in the pulling of the screws. But it is very easy to understand that the fact of the screws being able to rotate the balloon in a given direction is unquestionable, although men and captain were equally unable to move it in the right direction for escaping Prussian lines.

The difficulties experienced were so great that M. Richard stopped the experiment, and tried it again only after day-break, but with no other success than previously.

At 7 o'clock in the morning, altitude 65 centimetres, temperature 11° Fahr., cirrus was visible at a great height, cumulus down below, and stratus covering the earth.

At 11 o'clock only one sack of ballast was left. The balloon stopped its descent; voices of peasantry were heard from above the stratus. They cry "Versy; commune of Chigny." The balloon emerging in stratus, fell rapidly by condensation. All the ballast was thrown away, and the balloon ran horizontally for two miles. The guide rope only had been thrown; then the grapnel was thrown out. The wind was so strong that the grapnel rope was broken. The screws and wheels had been thrown overboard, but the car incliners and the screw axes project outside. One of these comes into contact with the ground, the car is upset, and the crew are dragged under it for a length of time, 600 yards. The balloon is stopped by the loss of gas and the peasantry. The three sailors are slightly injured, the captain is left for dead. The sailors, helped by the peasantry, make their escape, and conceal balloon, car, and despatches in the woods. The captain is brought like a corpse into a neighbouring town, but is found to be alive. He is cured, and sent secretly into Lille, where the balloon arrived two days later.

W. DE FONVIELLE

NOTES

AT a recent meeting of the American Philosophical Society it was resolved "That a committee, consisting of the President of the Society and five members, be appointed, whose duties it shall be to consider and report whether it is desirable, and if desirable, whether it be practicable, to establish in the City of Philadelphia, under the auspices of the Society, an Observatory, astronomical and physical, either or both; and if so at what cost, on what site, and what instruments are requisite for such purposes, and at what cost such instruments can be procured." We suppose such a proposal for England would be looked upon as a joke, and yet already we cannot compare with America in our observing power.

WE are informed that the Royal Commission on Scientific Instruction and the Advancement of Science have their First Report nearly ready.

DR. J. CLERK MAXWELL, F.R.S., was elected yesterday to the Professorship of Experimental Physics in the University of Cambridge.

It will have been observed that Sir F. Goldsmid carried his motion in the House of Commons last week: "That, in the opinion of this House, young men qualified by character and attainments for admission into the service of the Government of India as civil engineers, ought not to be excluded from such service by reason of their not having been educated at a Government College." If the facilities afforded by existing institutions are not found sufficient for the training of practical engineers, it is quite right that the Government should step in and supply the deficiency; our recent article on the subject shows whether the Institute of Civil Engineers is alive to the wants of the time in this respect. And if the Government establishes such a College, it is quite right that it should examine all candidates who present themselves, and give diplomas to those who pass them with credit; otherwise, it shows but little faith in its own system of education. Mr. Lowe has well pointed out that the Government will place itself altogether in a false position if it abandons its intention with reference to the proposed College, and yet takes no notice of the want of adequate instruction in the existing institutions. A leading article in the *Engineer* of last week on the subject points out that the idea of a competition between the Royal Engineers and the proposed College is a bugbear.

The number of candidates for admission to the Royal Society this year is fifty.

The members of the French Institute have learned with deep regret the death of one of its most celebrated members. M. Lartet died in the department of the Gers during the investment of Paris. It is in that very department that he discovered an immense quantity of fossils at Saint Salut. M. Lartet was professor of Palæontology at the Museum of Natural History, filling the place of the lamented d'Archiac. He was ill from the time of his nomination, and was unable to deliver a single lecture except his inaugural address. M. Lartet is known to the whole scientific world by an immense quantity of academic and scientific memoirs. His only work of consequence was published in connection with Mr. Henry Christy, an English merchant well known for his love of geology. That publication, which marks a starting point in palæontological inquiries, is called *Reliquiæ Aquitanicæ*, and cost the late Mr. Christy an immense sum of money.

We are very glad to observe that a fund is being raised in this country for the relief of French horticulturists and gardeners who have suffered by the recent war. Many of them have been reduced to a deplorable plight, their gardens, greenhouses, and orchards having been completely destroyed. Their condition presents a strong claim on their more fortunate *confrères* in this country. Contributions may be made in money, plants, cuttings, grafts, stocks, seeds, tools, mats, &c., and it is urgently requested that subscriptions in money be forwarded at once to the treasurer, Mr. G. F. Wilson, F.R.S., Heatherbank, Weybridge Heath, or to the honorary secretary, Rev. H. H. Dombrain, Westwell Vicarage, Ashford, Kent.

The impulse given to the study of Natural Science at Rugby is already bearing fruit. Mr. R. J. Williamson, who was elected to a Natural Science Studentship at Christ Church, Oxford, on the 4th, and Mr. C. J. Taylor, who obtained Miss Burdett Coutts's Geological Scholarship on the third of this month, were both Rugbeians. Including these, Rugby has had six Natural Science Honours during the last twelve months, viz., two Oxford "Firsts," one Cambridge "First," two Christ Church Studentships, and the Geological Scholarship. All this is encouraging for the future.

The *Bookseller* records the death at Dartford, at the age of eighty-two, of Mr. Augustus Applegarth, the eminent mechanist and inventor, to whom the world at large and the printing trade in particular are largely indebted for his improvements in the printing-press. Until substituted by Hoe's American machine, the *Times* was printed from an Applegarth, which printed from 8,000 to 10,000 copies per hour. Mr. Applegarth took out no fewer than eighteen patents for various purposes, including three for the printing of bank-notes, and for printing silk; but, like many inventors, although he enriched others, he failed to secure a fortune for himself.

M. Sorrel, one of the youngest members of the Observatory, has been a victim of the privations endured during the investment of Paris. He was engaged in the artillery of the National Guard. He had made one ascent on board the "Géant" and another on board the "Pole nord."

The cattle plague is raging amongst the herds which were congregated for the revictualling of Paris, and the carcases of dead animals are every day brought out in open carts, and conducted to Monfauçon to be buried. It appears that the same plague followed the invasion of 1814. M. Bouley, a member of the French Institute, contended in its last sitting that the meat of those animals could be eaten with impunity, and he said in support of his argument that cases of plague were discovered during the investment of Paris, and that the animals were not thrown away as useless. But it must not be forgotten that the mortality during the siege was very high, and that a part of the deaths may possibly be attributed to the bad quality of the meat taken from infected animals.

The weather at Paris is now very mild, and some fears are expressed of an outbreak of epidemic, in consequence of the burial of so many dead bodies of men and horses round Paris. It is supposed that 200,000 men and more than 100,000 horses were killed, besides 60,000 persons who died from different affections.

One of the most interesting scientific novelties of the day is the discovery of a true bone cave near Phœnixville, Pennsylvania, by Mr. C. M. Wheatley, reported in *Harper's Weekly*. The remains of animals, all extinct, are quite abundant and varied, and include bones of mastodon, horse, mylodon, and other forms, and are in great part entirely new to science. A preliminary report upon them, by Prof. Cope, was to appear in the March number of the *American Journal of Science*.

The same journal refers to the explorations made during the past summer in the western territories of the United States by the parties of Prof. Hayden and Prof. Marsh, the latter of whom has just published an interesting *résumé* of his geological observations. The principal field of his labours, as already stated, was the neighbourhood of Fort Bridger, among certain freshwater deposits from an ancient lake, the strata of which formed a thickness in places of at least 1,500 feet. Vertebrate remains of great variety were found entombed in these deposits, differing in marked features from those belonging to the Miocene basin east of the Rocky Mountains. In the latter bones of ruminating animals were especially abundant, while fishes and reptiles, with the exception of a single species of tortoise, were entirely wanting. In the Fort Bridger basin, on the other hand, reptilian life was in great development, and was represented by crocodiles, tortoises, lizards, and serpents, together with numerous fish, while many mammals, allied to the tapirs, as well as other small quadrupeds, occupied its borders. A detailed report of this exploration will be found in the March number of the *American Journal of Science*.

Lieutenant Payer, well known for his geological investigations in the Alps, has lately communicated some facts in regard to discoveries in Greenland by the late German expedition, of which he was a member; and in this he calls attention especially to the probability of the hypothesis that Greenland is essentially a congeries of islands similar to that west of it, and not a huge continental mass, as has been supposed by most authors. One strong evidence of this he considers to be furnished by the deep inlet discovered by the expedition, previously unrecorded on any chart, and which received the name of Emperor Francis Joseph's Fiord. This was found to extend deep into the interior of the land, continually opening into new arms, and widening in places until it was traced out for over one-third of the estimated breadth of Greenland, and without any indication of coming to an end. Indeed, in a south-westerly direction it opened out into what looked like a great basin into which the fiord itself emptied. The circumstance also that the saltness of the fiords is generally greatly diminished by the fresh-water streams pouring into them when they are simply *cul-de-sacs*, and the fact that the great Greenland fiord, notwithstanding the enormous addition of fresh water, retained all its saltness, pointed to a maritime communication with the opposite side of the country. Time was not allowed to the party to prosecute the exploration of this supposed strait; but it is believed, as stated, that it finds its opposite opening in Baffin's Bay. Another still more potent argument in favour of the assumption that Greenland is a congeries of islands, and not a continent, was found in the apparent absence of great longitudinal valleys, such as usually characterise continents, these being entirely wanting in the north-eastern part of Greenland.

WE understand that the collection of books belonging to the late A. H. Haliday, A.M., has been left by his will, dated in 1847, to the Royal Irish Academy. This collection is very rich in rare entomological tracts, and it is expected that a catalogue of it will be formed under the directions of the librarian of the Academy. Any duplicates of works at present in the library of the Academy are to go to the library of the Natural History Society of Belfast. The entomological collection of Mr. Haliday was bequeathed to the Museum of Trinity College, Dublin. This collection chiefly consists of British Diptera and Hymenoptera, and contains the type specimens of the many classical monographs and papers of Mr. Haliday. It also contains the results of some years' collecting in Italy, and especially the insects, many of them of great interest, taken during a tour in Sicily in 1868 by Mr. Haliday and Professor E. P. Wright. Unfortunately the collection is still in store or collecting boxes, and is for the most part unnamed, the localities of the European insects, which, however, form far the smallest portion of the collection, being indicated only by dates. We hope soon to be able to report what steps will be taken to have this collection named and arranged, knowing well that the authorities at Trinity College, Dublin, will not be slothful in this matter.

A COMMITTEE has been raised for the purpose of collecting subscriptions to present Mr. John Banting Rogers with a testimonial, as a mark of the high appreciation in which the shipping community of this country hold his untiring labours in the introduction of his valuable invention for life-saving purpose.

A CORRESPONDENT calls our attention to a state of things in the village of Woking which appears to require the notice of the Government inspector. He states that the drainage from the convict prison at Woking and from the gas-works is allowed to flow into an open meadow, which has become perfectly saturated with it. Fever has been prevalent in the neighbourhood for the last two years, and small-pox is now added. At the neighbouring village of Horsell a school of 200 children has been closed in consequence. As usual, it seems impossible to fix on anyone the responsibility for abating the nuisance.

CAPTAIN C. F. HALL is busily engaged in fitting out his vessel for his cruise next summer, and will be amply provided with everything necessary for his comfort and the success of his enterprise. It is understood that Dr. David Walker, the well-known companion of Sir Leopold M'Clintock during his expedition in the *Fox* in search of Sir John Franklin, will accompany Captain Hall in charge of the scientific department.

DR. A. W. EICHLER, the Editor of Martius's "Flora Brasiliensis," has been appointed Professor of Botany and Director of the Botanic Garden at Graz in Austria. No change will be necessary in the editing of the magnificent work under Prof. Eichler's charge.

THE region bordering upon the Black Sea has long been known to be full of antiquarian treasures of the highest interest, as evinced by the superb reports published from time to time at the expense of the Russian Government. A late exploration of the peninsula of Toman, situated between the Black Sea and the Sea of Azov, in continuation of previous researches, has brought to light many striking objects, particularly of those belonging to a past period of Greek art, and consisting of gold ornaments, sarcophagi, terra cotta statuettes, &c.

IN the Intercolonial Exhibition, held last year in Sydney, New South Wales, much interest and curiosity were felt in the specimens of wine exhibited. The report of the jury on the Victorian produce was highly satisfactory, more especially with regard to those wines retailed in Melbourne at 2*d.* and 4*d.* per tumbler. These wines are said to compare more than favourably with the cheap wines in general consumption in the wine countries of Europe, and promise ere long to supplant the use of beer and spirits in the classes most accustomed to use and abuse those beverages. For experience has long proved that men will drink wine in hot and dry climates in preference to all other beverages if they can get it abundantly, cheap, and good in its kind. The jury say that the cheap and wholesome wines sold in Melbourne at the above prices all over the city, and even a better class of wine retailed at 1*s.* per quart bottle, are the outward evidences of the hold which pure wine is taking on the masses in Victoria.

IT would appear from a communication in *Le Journal de Quebec* that the sea is steadily swallowing up the land at St. Thomas, and possibly other points on the lower St. Lawrence, a correspondent of the *Engineer* asserting that at low tide, some thirty years ago, he saw the ruins of the third church built in that locality within the space of two hundred years, and that since the battues, or banks covered by the tide, have advanced from one to two leagues into the interior.

MEAT-PRESERVING appears to be getting a profitable branch of trade in all countries where stock abounds or pasture exists. A new company with a capital of 50,000*l.*, under the title of the "Victoria Two-fold Bay, and London Meat-preserving Company" has been started in Melbourne. The meat is to be preserved by a process of cooking *in vacuo* by which air and moisture is drawn from the inside of the tins during the cooking.

THE Monthly Notices of Papers and Proceedings of the Royal Society of Tasmania for March, April, and June, 1870, contain several valuable articles, including Contributions to the Phytography of Tasmania, by Dr. Ferd. von Müller; and some additional Observations on more recent changes which have taken place in the star η Argus and its surrounding nebula (with diagrams), by Mr. F. Abbott.

THE great booksellers like Hachette and Co. have been surprised to learn that their branch offices in occupied districts had transacted an immense amount of business. The reason is singular enough, and worthy to be noticed. The Prussian soldiers are learning the French language, and are purchasing an immense number of books. There is a new market opened for French authors, an unforeseen consequence of bloody defeats in the field.

AT one of the sittings of the French Academy, Dr. Felix Rochard proposed to establish on the Seine floating ambulances for the wounded as being probably more free than common hospitals from miasmatic influence. The proposition was warmly supported by Baron Larey, the great practising surgeon.

PAPERS ON IRON AND STEEL

II.

THE BESSEMER PROCESS (CONTINUED)

IN the first part of this paper * I described the facts of the Bessemer process, and now proceed to a theoretical examination of these. In order to do this at all satisfactorily, it is necessary to have, at the outset, a clear idea of the composition of the raw materials,—the pig-iron and the spiegeleisen. I insist the more urgently upon this, because the descriptions or definitions of cast-iron or pig-iron usually given in our chemical text-books are by no means satisfactory, and are frequently erroneous.

The following are the results of my own analyses of fourteen brands of pig-iron and five brands of spiegeleisen, all of which are rather extensively used in the manufacture of Bessemer steel. In addition to the substances there determined, most of the pigs contain a small quantity of calcium, but this and the small traces of the metals of the other alkaline earths, and of the alkalis, were not determined, as the analyses were made for commercial purposes, and I have not been able to detect any practical modifications in quality of the finished iron or steel, which is due to the presence of these metals in the pig-iron. For this reason the statement of "iron by difference" is but an approximation, and somewhat in excess.

Composition of Bessemer Pig-Irons

No.	Combined Carbon.	Graphite.	Silicon.	Phosphorus.	Sulphur.	Manganese.	Iron by Difference.
1	0·60	4·12	1·92	0·10	0·06	0·32	92·88
2	trace	3·52	3·10	0·07	0·06	0·30	92·95
3	0·70	2·68	3·60	0·09	0·12	1·16	91·65
4	0·55	1·85	3·60	0·13	0·18	1·22	92·47
5	0·55	1·92	3·65	0·09	0·13	none	93·66
6	0·75	2·00	3·36	0·10	0·23	trace	93·56
7	0·54	2·20	3·15	0·10	0·26	2·00	91·75
8	0·72	2·10	2·90	0·06	0·16	1·00	93·06
9	0·62	4·00	1·40	0·02	0·06	0·38	93·52
10	0·50	3·00	2·00	0·03	0·10	trace	94·37
11	0·20	2·80	2·33	0·02	0·10	1·92	92·63
12	trace	3·20	1·58	0·11	0·12	2·22	92·77
13	0·37	1·95	4·08	0·15	0·23	1·15	92·06
14	1·25	1·65	2·15	0·24	0·21	1·10	93·40

For commercial reasons, which will be readily understood, I abstain from publishing the names of the above brands. No. 12 is a Swedish pig-iron; all the rest are English hæmatite pig-irons, made expressly for Bessemer purposes. Nos. 9, 10, and 11 produced exceptionally good steel; Nos. 1, 2, and 3, good average qualities; No. 4, inferior; No. 13, *very* inferior; No. 14 produced such bad steel that the whole parcel was returned, though it came from a well-known firm, it was of the same brand as No. 4.

Composition of Spiegeleisens

No.	Combined Carbon.	Graphite.	Silicon.	Phosphorus.	Sulphur.	Manganese.	Iron by Difference.
1	4·10	0·45	1·23	0·12	0·16	4·60	89·34
2	4·10	0·40	0·96	0·03	0·26	5·86	88·39
3	4·50	0·40	0·88	0·04	0·10	9·61	84·47
4	4·10	0·42	0·65	0·05	0·15	8·64	85·99
5	3·00	0·70	0·14	0·04	0·07	6·44	89·61

No. 3 is the best of these; No. 4, the next in quality, rather better than average; No. 2, rather below average; No. 1, inferior quality; and No. 5 so poor that it was rejected.

* NATURE, Vol. iii. No. 63, p. 211

Excluding the rejected samples, the average of the above is as follows:—

Average Composition of 13 Brands of Bessemer Pigs

Combined Carbon	0·47
Graphite	2·72
Silicon	2·84
Phosphorus	0·08
Sulphur	0·14
Manganese	0·90
Iron by difference, about	92·85
	100·00

Average Composition of four Brands of Spiegeleisen

Combined Carbon	4·20
Graphite	0·42
Silicon	0·93
Phosphorus	0·06
Sulphur	0·17
Manganese	6·63
Iron by difference, about	87·59
	100·00

The sulphur of this average of the spiegeleisens is excessive, being raised unduly by the very unusual quantity contained in No. 2: 0·12 per cent. would state the general average more correctly. In like manner the phosphorus average is raised by the excessive quantity in No. 1. Excluding this the average is reduced to 0·04.

I will pass over the small amount of chemical change which results from the mere melting of the pig and speigeleisen in the cupola, and regard the above as the composition of the material which enters the converter. When a mixture such as these Bessemer pig-irons is fused and exposed to the action of atmospheric air, the silicon is the most readily oxidised, silicates of iron and manganese are formed, which separate and float on the surface, forming the "cinder." The carbon oxidises simultaneously with the silicon, but in a much smaller degree, until the silicon is nearly all burnt out. When the silicon is reduced below one per cent., the combustion of the carbon takes the lead, and the small remainder of silicon is but slowly oxidised, the last traces resisting oxidisation with considerable stubbornness.

I have made some special investigations of this subject, and shall show in the course of another paper that manganese is remarkably efficient in removing these last traces of silicon. I should also mention that the above-stated generalisations respecting the prior combustion of silicon and the suppression of carbon combustion by the presence of unburnt silicon, are based chiefly on examinations I have made of the actions which take place in the "refinery;" the difference between the Bessemer converter and the refinery being, that in the one, air is blown upon or a little below the surface of the melted pig-iron, while in the other, it is blown through it from below, and thereby acts with far greater efficiency and rapidity; the *kind* of action is, however, the same in both cases, the difference is only in *degree.*

In order to test the accuracy of the above conclusions, I have requested my late assistant at the Atlas Works, Mr. G. C. Barker, to make analyses of the Bessemer material during different stages of the same blow. This he has kindly done, and the following are his results. The carbon, silicon, sulphur, phosphorus, and manganese only are determined.

The first column shows the percentage of these constituents in the pig-iron after being melted just before being poured into the converter.

Second, the same after six minutes blowing.

Third, the same after twelve minutes blowing.

Fourth, the same when the blowing was finished, but before the spiegeleisen was added.

Fifth, the finished steel when poured into the ingot moulds.

	1	2	3	4	5
Combined carbon	1·000	3·040	1·640	0·190	0·370
Graphite . . .	2·570	trace	trace	trace	trace
Silicon	2·260	0·955	0·470	trace	trace

Phosphorus . .	0·073	0·070	0·070	0·070	0·059
Manganese . . .	0·410	trace	trace	trace	0·540

We shall now be able to understand the changes I have described as occurring in the flame. Before the full combustion of the carbon can commence, there is about $2\frac{1}{2}$ per cent. of silicon to be converted into silicic acid. In a charge of 6 tons this amounts to 3 cwt. For the complete combustion of this, nearly $3\frac{1}{2}$ cwt. of oxygen, or about 14 cwt. of atmospheric air, is necessary. My explanation of the smaller and less brilliant flame that at first roars from the mouth of the converter is that it is mainly a silicon flame, mingled, however, with a small proportion of carbon flame; that the amount of silicon combustion goes on diminishing, and in a proportionate degree the carbon combustion increases, as the demand of the silicon upon the oxygen of the blast diminishes in consequence of its less abundant diffusion among the melted iron.

I shall not be surprised if this explanation is controverted, as in offering it I fly in the face of the spectroscope, which has made such glorious conquests that modern philosophers are disposed to trust it as implicitly as successful soldiers rely upon the general who has led them continually to victory; but without failing in due deference to those who are more skilful than I am in the use of this instrument, I am satisfied that in this and other cases where the question has been to determine the presence or absence of the *metalloids*, the *negative* replies of the spectroscope have been too hastily accepted. Prof. Roscoe, who devoted a considerable amount of time and labour to the spectroscopic examination of the Bessemer flame, says, "Those who are practically engaged in working this process would like spectrum analysis to do a great deal more; they would like to be told whether there is any sulphur, phosphorus, or silicon in their steel; questions which, unfortunately, at present spectrum analysis cannot answer, for this very good reason, that these substances do not appear at all as gases in the flame, but that they either remain unvolatilised in the molten metal, or swim on its surface in the slag of the ore; and, consequently, the lines of these bodies are not seen in the spectrum of the flame." Dr. Watts's observations and conclusions accord with those of Prof. Roscoe.

If by the above Prof. Roscoe is to be understood as asserting that no portion of the Bessemer flame at any period of its existence is due to the combustion of silicon, or that silicon is not present in the Bessemer flame, I must very decidedly affirm that such conclusion is erroneous. I do not for a moment question the accuracy of the observations of both Prof. Roscoe and Dr. Watts. I merely maintain that the absence of "the lines" of silicon in the spectrum of the flame does not prove its absence as a constituent in producing such flame, and for the following reasons:—

We know that that the silicon existed in the pig-iron in the proportion already stated, and that although a very small quantity of that which ordinary analysis detects may have existed as entangled silicate in the pig, and another small portion is of course oxidised in the cupola, the bulk of it enters the converter as unoxidised silicon, and that it is oxidised and converted into silicic acid during the blow. We also know that silicon when heated in air or oxygen burns brilliantly, and that the product of such combustion when heated with a blast such as that which supplies its oxygen in the Bessemer converter, is sufficiently volatile to form concretions in the throats of furnaces, which have been compared to natural chalcedony. Besides this a large quantity of solid matter is mechanically forced into the flame, and is seen above as a red smoke, which, without the slightest indication of unburnt carbon, is often sufficiently dense to hide the mid-day sun. The greater the quantity of silicon in the pig the more dense is this red smoke, which appears to consist of silicate and peroxide of iron. I maintain, therefore, that silicon is there, and that it must contribute to the luminosity of the flame, though it shows no characteristic "lines" in the spectrum.

Under such circumstances, we have no good *a priori* reasons for looking for the silicon *lines*; a *continuous spectrum* being that which we are theoretically justified in anticipating as the result of such combustion of silicon, and this is exactly what the spectroscope reveals. The spectrum of the Bessemer flame at the commencement and early stages of the blow is of a most uncommunicative continuous character: occasional flickerings and vanishing ghosts of lines and bands come and go with perplexing irregularity; and even the brilliant and ever obtrusive sodium lines do not appear at this stage, but commence with spasmodic flashings across the spectrum at about the period when the elongation and brightening of the flames which I have described is most decidedly taking place. When the flame has reached its maximum of extension and brilliancy, the sodium lines cease their intermittent flashings, and become a steady stream of light, the lithium band appears (though not in every blow), and the whole spectrum becomes striped, but the continuous spectrum still remains as the permanent background.

My general reason for questioning the negative conclusions of the spectroscope in reference to silicon and the other metalloids is, that these bodies usually give a continuous spectrum when, as elements, they combine freely with oxygen, as in direct unrestrained combustion under ordinary pressure in the open air. It appears to me that there is thus presented a broad distinction between the spectra of the metals and of the non-metallic elements, which is of great practical importance, and which has not been sufficiently considered, when conclusions have been based on negative spectroscopic results. I have already, in chapter 13 of "The Fuel of the Sun," referred to the worthlessness of the negative evidence of the spectroscope in reference to the non-existence of the metalloids in the sun, and maintain that "they may all be there though the spectroscope should not detect one of them." The mere fact that nothing but metals (I include hydrogen with these) should have been discovered in the sun is very suggestive.

W. MATTIEU WILLIAMS

SOCIETIES AND ACADEMIES

LONDON

Royal Society, February 23.—"On the Thermo-electric action of Metals and Liquids," by George Gore, F.R.S. It is well known that the degree of rapidity with which a metal immersed in an acid, alkaline, or saline liquid is corroded varies considerably with the temperature, and that the speed of corrosion usually increases with the heat; also a few experiments have been published (Gmelin's "Handbook of Chemistry," vol. i. p. 375) showing that changes of electrical state occur in metals under such circumstances; but a further examination of the relations of the temperature and chemical change to the electrical state has not, that I am aware, yet been made.

In an investigation on the development of electric currents by unequally heated metals in liquids (*Phil. Mag.* 1857, vol. xiii. p. 1), I found that hot platinum was electro-negative to cold platinum in liquids of acid reaction, and positive to it in alkaline ones, provided in all cases chemical action was completely or sufficiently excluded. In the present experiments I have endeavoured to ascertain what electrical changes are produced in cases where chemical action more freely occurs, and I have therefore employed not platinum plate, but plates composed of a metal (copper) which is more easily corroded.

The following are the general results arrived at.

The chief fact brought out conspicuously by the experiments with copper dishes is, that in many cases an increase of chemical action produced by heat instead of making the hot metal electro-positive makes it considerably negative.

The results show that hot copper was positive to cold copper in the following liquids:—hydrochloric, hydrocyanic, boracic, and tribasic ortho-phosphoric acids; chloride of copper (weak solution); chloride of cobalt; chloride of manganese; chromic acid; chloride of chromium; sulphate of zinc (weak solution); sulphate of magnesia; chloride of calcium; nitrate and chloride of strontium; chloride of barium; nitrate of sodium (strong solution); chloride, iodide, carbonate, and biborate of sodium; sulphate of sodium (strong solution); tribasic phosphate of sodium; nitrate, chloride, and chlorate of potassium; bromide of potassium (strong solution); iodide of potassium (strong solution); carbonate, acid carbonate, and bichromate of potassium; aqueous ammonia; chloride of ammonium; cyanide and ferrocyanide of potassium; acetate of zinc; and acetate of sodium. And negative in the following ones:—nitric, chloric, hydrobromic, hydrofluosilicic, and sulphuric acids; ferrous sulphate; chloride of copper (strong solution); sulphate of copper; sulphate of zinc (strong solution); nitrate and iodide of sodium (weak solutions); bromide and iodide of potassium (weak solutions); iodate of potassium; chrome alum; nitrate of ammonium; oxalic, acetic, tartaric, and citric acids. The number of liquids in which hot copper was positive was thirty-six, and those in which it was negative was twenty.

In several instances where the hot metal was negative with a weak solution, it became positive with a strong one; for instance, with sulphate of zinc, nitrate, iodide, and sulphate of sodium, bromide, and iodide of potassium; but with chloride of copper the reverse occurred. These results may be connected with the fact that in weak neutral solutions the chemical action is generally the most feeble, and therefore interferes the least with the direct influence of the heat in producing electric currents.

The influence of free hydrochloric, hydrocyanic, boracic, ortho-phosphoric, and chromic acids, was to make the hot copper positive; whilst that of nitric, chloric, hydrobromic, hydrofluosilicic, sulphuric, and some of the organic acids was to make it negative.

In consequence probably of the small amount of interference by chemical action in solutions of oxalic, acetic, tartaric, and citric acids, the direct influence of the heat made the copper negative, similar to its influence on platinum, in all acid liquids which do not attack that metal.

The nature of the acid in a salt appears to exert much more influence than that of the base on the direction of the current; for instance, in nearly all chlorides, including those of a considerable variety of bases, hot copper was positive, probably because copper is more readily attacked by acids than by bases.

In all decidedly alkaline liquids the hot copper was positive; this is similar to the behaviour of platinum in such solutions, and is probably due to the same course, viz. the direct influence of the heat, as well as to chemical action.

The results also show that the quantity of the current obtained with any given liquid generally increases with the number of molecules of the substance contained in the solution; in some cases, however, as with sulphuric acid, carbonate of potossium, chloride of ammonium, and acetate of zinc, there was a limit to this increase; and beyond that limit the quantity of the current decreased up to the point of saturation of the liquid.

In the great majority of cases the value of the deflection increased much more rapidly than the strength of the solution, particularly with solutions of sulphate of magnesia, and also of hydrochloric acid and of chloride of sodium, probably because two causes operated, viz. increased strength of solution and diminished resistance; in a very few cases, however, the opposite result took place, as with solutions of chloride and nitrate of strontium.

Inversions of the direction of the deflection by difference of strength of the liquid occurred with solutions of chloride of copper, sulphate of zinc, nitrate, iodide, and sulphate of sodium, bromide, and iodide of potassium.

Irregularities of the amount of deflection were very apt to take place with liquids which gave strong deflections, or which acted much upon the copper plates (for instance, nitric acid), especially if bubbles of air remained under the plates, or the dishes were wetted on their side above the liquid by the solution.

In certain acid liquids, viz., nitric, chloric, hydrobromic, hydrofluosilicic, and sulphuric acids, the hot copper was strongly negative (notwithstanding the chemical action upon it was distinct, and in some cases even strong); this is similar to the electrical behaviour of platinum in such liquids, and may be attributed either to the more direct influence of the heat alone (such as occurs with platinum plates), or to a different influence of the chemical action produced by the heat. Both these causes probably operate in such cases.

It is probable that in all cases where the hot copper was positive in liquids of strongly acid reaction, the positive condition was due to chemical action alone.

With some liquids, especially with solutions of hydrocyanic, boracic, acetic, tartaric, and citric acids, the deflections were very feeble, and the chemical action on the plates not perceptible; whilst with others, such as nitric and chloric acid, solutions of the chlorides of strontium, sodium, potassium, and ammonium, and of carbonate, acid carbonate, and cyanide of potassium, the deflections were considerable, and the chemical action distinct, and in some cases strong. In none of the liquids (except hydrobromic and chromic acids) did the hot plates appear to be *less* stained or corroded than the cold one; probably, in all cases, it was the most corroded, although in some cases the corrosion was not perceptible.

The amount of deflection was not always proportionate to the amount of chemical action; for instance, with solutions of chloride of copper and iodate of potassium there was considerable corrosion, but only feeble currents, probably because the plates became covered with a badly conducting film, whilst with hydrochloric acid, chloride of cobalt, chloride of manganese, and nitrate of potassium, the reverse occurred.

I consider the currents in all these experiments of difference of temperature to be due either (1) to the direct influence of heat, the effect of which is to make the hot copper negative in acid liquids and positive in alkaline ones (see *Phil. Mag.* 1857, vol. xiii. p. 1); (2) to chemical action, which sometimes overpowers the direct influence of heat and reverses the effect; or (3) to both these influences combined. The more ultimate cause, however, of the phenomena in these causes must be sought for in the *molecular movements* produced by heat in the metals and liquids.

The current obtained with copper plates were no doubt influenced in their amounts (if not also in their direction) by the oxidising action of the air upon the liquid and metal at their line of mutual contact, for we know that metals in contact with liquids oxidise much more quickly if oxygen has access to their wet surfaces; and the currents were also influenced by the action of unequal temperature upon the air-contact line, for we know that wet metals oxidise still more rapidly if heat is applied.

General Conclusion.—The electric currents produced by the direct influence of unequal temperature or friction of platinum or copper electrodes, in conducting liquids which do not act chemically upon those metals, have their origin in temporary changes of cohesion of the layers of metal and liquid which are in immediate and mutual contact, and may be considered as a very delicate test of the kind and amount of temporary molecular movements produced by those causes.

"Further Experiments on the effect of Diet and Exercise on the Elimination of Nitrogen," by E. A. Parkes, M.D., F.R.S.

"Magnetic Observations made during a Voyage to the North of Europe and the Coasts of the Arctic Sea in the Summer of 1870," by Capt. Ivad Belavenetz, I.R.N., Director of the Imperial Magnetic Observatory, Cronstadt.

"On the Mutual Relations of the Apex Cardiograph and the Radial Sphygmograph Trace," by A. H. Garrod, of St. John's College, Cambridge.

Geological Society, February 22.—Mr. Joseph Prestwich, F.R.S., president, in the chair. Mr. John Thornton Harrison, C.E., and Mr. M. Hawkins Johnson, were elected Fellows of the Society.—The following communications were read:—1. "On supposed Borings of Lithodomous Mollusca," by Sir W. C. Trevelyan, Bart., M.A., F.G.S. The author referred to Mr. Mackintosh's paper on this subject (*Q. J. G. S.* vol. xxv. p. 280), and stated his conviction, from examination of specimens, that the holes in question are the work of *Helices*, or other terrestrial Mollusca. He ascribed the same origin to the so-called "*Pholas*-borings" in the limestone at Orme's Head and elsewhere. He considered length of time to be a necessary element in the formation of these holes. The author also remarked that he had suggested a glacial origin for the terminal curvature of the laminæ of slate-rocks as early as 1849. Mr. Gwyn Jeffreys read extracts from a work published by the Rev. Mr. Hodgson in 1827, on the Natural History of Northumberland, in which these borings in limestone were referred to the action of snails. Mr. Jeffreys considered the foot to be the sole instrument employed by the boring Mollusca in excavating their burrows. He exhibited specimens of Lias from Lyme Regis perforated by *Pholas*, and of hard limestone from Malta perforated by *Lithodomus*, and remarked, in connection with the notion that asperities on the shell might be boring agents, that the shell of *Lithodomus* is perfectly smooth. Prof. Ramsay mentioned that he had seen *Helices* taken out of these holes at Tenby by Dr. Buckland, who believed that the snails effected the perforations by the agency of an acid. Mr. Charlesworth thought that if so much uncertainty could prevail upon such a subject, it threw great doubt upon some of the grandest generalisations of geology. He referred to the evidence connected with the glaciation of the Great Orme's Head, in which the origin of the perforations under discussion was of much importance, Mr. Darbyshire maintaining that they were the work of *Pholades*, while Mr. Bonney asserted that they were produced by snails. In the same way the origin of the celebrated borings in the Temple of Jupiter Serapis might be disputed, and the generalisation founded upon it rendered doubtful. Mr. Charlesworth noticed the necessarily small proportion of borers to the whole snail population of Britain, and remarked especially upon the absence of perforations in the chalk districts. He considered that repeated observations were necessary before this snail-engineering could be admitted, and suggested a systematic course of experiments. Mr. Boyd Dawkins suggested that the carbonic acid exhaled by snails in respiration might act upon limestones, and remarked that chalk weathers too rapidly to preserve the excavations.—2. "On the probable Cause, Date, and Duration of the Glacial Epoch of Geology," by Lieut.-Col. Drayson, R.A. In this paper the author started from the fact that the pole of the ecliptic could not be the centre of polar motion, as the pole varied in its distance from that centre. He indicated the curve which the pole did trace, and this curve was such as to give for the date 13,000 B.C. a climate very cold in winter, and very hot in summer for each hemisphere. The duration of the glacial epoch he fixed at about 16,000 years. The calculations resulting from this movement were stated to agree accurately with observation. Prof. Ramsay inquired whether the author's theory involved the recurrence of glacial epochs, and whether he considered the course of phenomena to be constant in early astronomical epochs. Rev. Osmond Fisher inquired whether the theory was founded on observed facts, or whether it was a purely physical theory. He also asked whether the line representing the change in the direction of the pole formed a re-entering curve, and whether the theory would account for the climate of Greenland in Miocene times. He suggested changes in the form of the earth which must have affected the direction of its axis. The President remarked upon the difficulty that arose from astronomical theories differing so much among themselves. He referred particularly to Adhémar's theory, and remarked that the difficulty connected with it is, that it invokes a recurrent cause, which must produce similar effects every 21,000 years, whilst there is very little evidence of glacial action during the whole long period of the Tertiary epoch. The author, in reply, stated that he could not go back beyond 30,000 years, but that he thought glacial conditions must recur. He had not astronomical data beyond 2,500 years, and these were very vague. The motion would be the same in kind, but uncertain in degree. His theory was based entirely upon observed facts. In laying down the curve, he considered it safe to go as far as the semicircle, as he had observations covering 40°; but he could not say whether the curve would be a re-entering one, although it showed a tendency that way, and would certainly be very nearly so. With regard to the change of climate of Greenland, as evidenced by its Miocene flora, he was not sufficiently versed in botany to pronounce an opinion. He remarked, in conclusion, that the distance of a planetary body from the sun did not seem to affect climate, and stated that Venus is at present suffering under a most severe glacial epoch.—3. "On Allophane and an allied Mineral found at Northampton," by Mr. W. D. Herman. In this paper the author gave analyses of an amorphous, translucent, reddish-yellow mineral, found incrusting sandstone in the ironstones of the Northampton sands, the comparison of which with Mr. Northcote's analysis of allophane from Charlton leads him to infer the identity of the two minerals. He also noticed a soft white substance found in certain joints in a section of the Northampton sand, and also referred to allophane by the late Dr. Berrell, who analysed it. This substance was said to occur not unfrequently in the inferior oolite of the Midland Counties. By analysis, it was shown to agree nearly with Samoite and Halloysite. Mr. David Forbes stated that he had found phosphoric acid in the first-mentioned mineral, which was perhaps the cause of its lustre. The mineral was probably not pure allophane. Prof. Morris suggested a chemical and microscopical examination of the strata above the places in which these minerals occur, which would probably reveal the conditions under which they have been formed. They were probably produced by the decomposition of silicates in the overlying rocks during the percolation of water. This applied also to the Charlton locality. Mr. Carruthers mentioned that allophane often fills the inflorescence of the Cycads of the Yorkshire Oolite, entirely destroying the vegetable structure, and that it also occurs in clay nodules from the coal-measures. Mr. Carruthers suggested that the decomposition of vegetable matter in clays might aid in the production of the mineral. —4. "Notes on the Peat and underlying Beds observed in the construction of the Albert Dock, Hull," by J. C. Hawkshaw, Esq., M.A., F.G.S. The Albert Dock is situated on the foreshore of the River Humber. The excavation for the dock extended over an area of about thirty acres, and they were carried down to a depth varying from 8 feet to 27 feet below low water of spring-tides. Beneath the more modern deposits of Humber silt a bed of peat, Hessle Clay, Hessle Sand, and purple clay, were successively met with. The peat was found at the west end of the Dock at the level of low water; at the east end the bed dipped so that the upper surface was found at eight feet below the level of low water. In the peat were found the remains of a fire, which the writer attributed to human agency. Oak-trees of large size were imbedded in the peat, some of which had grown where they were found, as was shown by the stools remaining with the roots penetrating the Boulder-clay beneath. In one oak-tree, five feet in diameter, a hole was found filled with acorns and nuts. Many of the nuts were broken open at the ends, and had evidently formed part of the store of a squirrel. Remains of Coleoptera were found, and one horn-core of a *Bos*. The excavation did not extend below the upper parts of the purple clay. Some of the borings, however, penetrated the chalk at a depth 85 feet below low water level, passing through a bed of sand 16 feet thick below the purple clay. Several thousand cubic yards of this sand were brought up into the foundations by springs of water which flowed up through old bore-holes. The abstraction of this sand from beneath the clay-bed caused it to subside many feet. The writer thinks that analogous subsidences may take place from natural causes; for instance, where large springs occur in tidal rivers. Two sections exhibited showed the beds above the chalk for a distance of rather more than a mile along the foreshore. The Hessle Sand was shown to thin out to the westward. It does not, in the writer's opinion, increase in thickness in that direction, as it was shown to do in a section already published in the Proceedings of the Society. The President remarked upon the singularity of the occurrence of a bed of ashes at such a depth in these deposits. Mr. Gwyn Jeffreys referred to the President's paper on the Kelsey Hill beds, and remarked on some of the mollusca obtained by Mr. Hawkshaw. Mr. Boyd Dawkins mentioned the occurrence of a submarine forest on the coast of Somersetshire, forming a layer of peat, beneath which was a land-surface, on which the forest had grown, and in which flint-flakes were found at Portlock and Watchet on digging through the peat. He remarked on the depression of the coast of Somersetshire within the human period, and suggested that the forest at Hull may have been contemporaneous with that of Somersetshire. Prof. Morris inquired whether any trees or roots were found as when growing. The shells obtained were estuarine. Prof. Morris remarked on a submerged forest near Whittlesey, with terrestrial plants and freshwater shells imbedded in the overlying clay. The author, in reply, stated that the trees had fallen where they grew. The general appearance of things led him to the belief that the fire which had destroyed part of the forest was of human production. The following specimens were submitted to the meeting:—Specimens of Allophane, from the Northampton Sands; exhibited by Mr. F. V. Runler, F.G.S. Specimens of Websterite, from the junction of the Tertiaries and the Chalk, near Bromley, Kent, exhibited by Mr. W. Whitaker, F.G.S. Specimens from the Peat-beds at the Hull Albert

Dock; exhibited by Mr. J. C. Hawkshaw, F.G.S., in illustration of his paper. Specimens of *Pholas*-borings from Lyme Regis, and of *Lithodomus*-borings from Malta; exhibited by Mr. J. Gwyn Jeffreys, F.R.S.

Chemical Society, March 2.—Prof. Williamson, F.R.S., president, in the chair. The following gentlemen were elected Fellows:—G. D. Harding, W. H. Hudleston, A. H. Mason, J. J. Nicolson. The following papers were read:—"On the distillation and boiling point of glycerin," by T. Bolas. It is known that when glycerin is heated under the ordinary atmospheric pressure so much as to cause ebullition it is more or less decomposed. This decomposition may be, however, prevented by a reduction of the pressure in the apparatus employed. The author has in that way found that pure glycerin boiled under a pressure of 12·5^{mm} at 179·5° C and under a pressure of 50^{m} at about 210° C.—"On the action of Heat on Silver Nitrite," by Dr. E. Divers. The products of this action consist principally of silver nitrate, reguline silver, and oxides of nitrogen. But the relative proportions of the quantities of these substances to each other, and consequently the composition also of the gaseous matter, vary considerably in different experiments. When the nitrite is heated in an open vessel over a lamp or in an oven at any temperature between 85° and 140° C. the result of the operation may be represented by the equation $3\ NO_2\ Ag = N_2\ O_3 + Ag_2 + NO_3\ Ag$. When, instead of an open crucible, a closely covered one is used, so that the gaseous and fixed products of decomposition may be kept for a time in contact, the ultimate change effected in this way approaches, though not closely, to what is expressed by the equation $2\ NO_2\ Ag = NO + Ag + NO_3\ Ag$. In a third series of experiments, where the nitrite was heated in a vessel only nearly closed, the facts observed show that there is a tendency to yield only metallic silver and nitrogen peroxide, thus: $NO_2\ Ag = Ag + NO_2$. From all his experiments Dr. Divers draws the conclusion that like other silver salts the nitrite splits up under the influence of heat into metallic silver and the acid radical or its components, and that silver nitrate, nitric oxide, and, perhaps, nitrous anhydride are formed only by secondary reactions. The fusion which occurs in the mass of heated nitrite so soon as it has undergone some oxidation causes the author to throw out the suggestion that the nitrate formed perhaps combines with the nitrite to a nitrite-nitrate or hyponitrate.—After the reading of the above papers Dr. Gladstone communicated some remarks on the "Relations of Chemical Reaction and Time." He had instituted most varied experiments bearing on this subject, and, in briefly mentioning some of them, he wished to call the attention of chemists to this wide field of inquiry. Hitherto experimentators seemed to have limited their observations to only the circumstances at, and the products with, which a chemical reaction begins and ends, all that happens between was left wholly unnoticed. How fruitful attention paid to the intermediate products of a reaction could be is seen in the beautiful results which Prof. Williamson had gained on his researches on Etherification. The President, Dr. Odling, Mr. Vernon Harcourt, and others concurred in Dr. Gladstone's view as to the importance of a closer study of this subject.

Anthropological Institute of Great Britain and Ireland, March 6th.—Dr. R. S. Charnock, Vice-president, in the chair.—The following new members were elected:—Messrs. C. P. L. Naidoo Garroo, Henry Cook, Joseph Sharpe, LL.D., Danby P. Fry, Charles Edward Moore, Jesse Tagg; and W. S. W. Vaux, F.R.S., an honorary member.—Colonel Lane Fox exhibited a flint implement from Honduras.—Mr. Edward Blyth exhibited some cloth from West Africa.—Mr. Josiah D. Harris read a letter from his son on some remains found in the Macabi Islands, Peru.—Mr. J. W. Jackson read a paper "On the Racial Aspects of the Franco-Prussian War." After some remarks on the Aryan and Semitic divisions of the so-called Caucasian race, the former being defined as the flower of a Turanian, and the latter of a Negroid root, the author said that in the present imperfect state of our knowledge, it was impossible to decide whether Europe or Asia should be regarded as the primal and appropriate habitat of the Aryan, although he inclined to the former hypothesis. Neither could we yet assign the date when, and the place where, the various sub-divisions of this great race originated, and so must be contented with the fact of finding Slavons, Iberians, Teutons, and Celts on their existing areas of occupation, when, like the flora and fauna that accompany them, they must be regarded as Telluric organs. From a rapid survey of the earlier periods of European history, it was shown that the Celtic area of Gaul and Britain must have been ethnically effected at the time of the Roman conquest, which civilised but did not physically regenerate the Provincials. This was effete at the Gothic conquest of the Empire, when the Gauls received a slight and imperfect, and the Britons an effectual, baptism of Teutonic bone and muscle. The result of this diversity of fortune is seen in the fact that France, which retained more of the refinement, and with this more of the corruptions, of classic culture than Britain, preceded the latter in the attainment of civilisation, and now, after some centuries of quasi-imperial leadership in literature, science, manners and taste, is once again sinking into national weakness as an inevitable result of racial exhaustion. Hence it is that she no longer produces master-minds in any department, not even in war. Where are the successors of Cuvier and La Place, of Corneille, Racine, and Voltaire? This ethnic collapse of France, however, does not necessarily imply a subsidence of the entire Celtic area of Western Europe, as Britain is still at her maximum of racial vigour, and, like Rome after the decadence of Greece, will probably inherit that portion of the mission of imperial leadership forfeited by her effete sister and former rival. The Germans cannot do this, having so recently attained to unification, and being consequently devoid of any great capital like London, which may serve as the future metropolis of cultivation. Their mental constitution is, moreover, not adequately synthetic for the mission of Imperial centrality, which must accordingly devolve on England, the geographical terminus of the great north-western march of empire from the Euprates to the Thames. Discussion having ensued, on the motion of Mr. Joseph Kaines, seconded by Capt. Pim, it was adjourned till the 20th instant.

Linnean Society, March 2.—Mr. G. Bentham, president, in the chair. The following papers were read:—On the Tamil Mames of Plants, by Rev. S. Mateer; Contributions towards a Knowledge of the *Curculionidæ*, by Mr. H. P. Pascoe.

Royal Institution of Great Britain, March 6.—Sir Henry Holland, Bart., M.D., F.R.S., president, in the chair. Messrs. W. Blenkin, J. Browning, E. Maynard Denny, F. A. Eck, Sir Frederick Elliot. K.C.M.G., Col. A. Lane Fox, Mr. P. Graham, Col. J. A. Grant, C.B., Mr. E. W. Grubbe, Dr. G. Harcourt, Capt. F. Helbert, Mr. G. W. Henderson, Mr. G. Middleton Keill, Dr. J. Kennedy, Mr. J. Macauley, Mr. K. R. Murchison, Mrs. Sheffield Neave, Mr. G. W. Royston Pigott, Mr. Eustratios Ralli, Mr. F. S. Reilly, Mr. W. C. Roberts, Mr. W. Dehague Routh, Mrs. W. C. Smith, Mr. T. Sowerby, were elected members.

MANCHESTER

Literary and Philosophical Society, February 7.—Mr. E. W. Binney, F.R.S., president, in the chair. "On the Organisation of an Undescribed Verticillate Strobilus from the Lower Coal Measures of Lancashire," by Professor W. C. Williamson, F.R.S., &c.—"The Tails of Comets, the Solar Corona, and the Aurora, considered as Electric Phenomena, part ii.," by Prof. Osborne Reynolds, M.A.—"Further Experiments on the Effects of Cold upon Cast Iron," by Peter Spence, F.C.S., &c.

February 21.—Mr. E. W. Binney, F.R.S., president, in the chair. "The Overthrow of the Science of Electro-Dynamics," by John Hopkinson, D.Sc. In science no theory should be considered unquestionable and no man's work held sacred from attack, and our scientific periodicals should afford the freest scope to discussions no matter how hostile to established notions. Still, it is evident that the journals ought not to publish everything that may come to hand; they should at least take care that a hostile critic understands the meaning of what he criticises. Two papers appeared last month in the *Quarterly Journal of Science* and the *Chemical News* respectively, in which the author (the Rev. Mr. Highton) somewhat summarily disposes of the science of Thermodynamics, fancying he has disproved the equivalence of heat and work. I will only trouble you with one or two quotations with a view to support my opinion that the papers in question ought never to have been permitted to appear in any journal pretending to scientific position. In the *Chemical News*, p. 42, we find, speaking of Joule and Scoresby's experiments on electro-dynamic engines—"They say that 'the quantities of zinc consumed' (that is, respectively, when the engine is at rest and doing work) 'being as a to b, $(a-b)$ represents the quantity of heat converted by the engine into useful mechanical effect.' Therefore, since on the supposition of a mechanical equivalent of heat a grain of zinc consumed equals 158 foot pounds, if x = pounds raised a foot high per consumption of a grain of zinc in the battery,—

$$x = \frac{(a - b)\ 158}{a}$$

Hence the authors draw the conclusion :—'Therefore when b vanishes, or becomes infinitely small, the economical duty is a maximum.' Certainly this is a most startling result; that the maximum of work should be done when no zinc at all is consumed." The last sentence is a mis-statement of the conclusions of Joule and Scoresby's paper, in which (*Philosophical Magazine*, vol. 28, p. 451) it is stated that "the economical duty will be a maximum when b vanishes or becomes infinitely small in comparison with a. In this case x = 158, while the power of the engine will become infinitely small with regard to work performed in a given time." Comparing the phrases "economical duty" and "maximum of work," as he uses them, he evidently confuses the duty of an engine with the whole work done by it. A little further on we have—"They calculate the maximum theoretical power of a grain of zinc to be 158 foot pounds, and yet using permanent magnets, which, by their own statement, were so badly constructed as to have only a quarter the power they ought to have had, with the poles of the electromagnets never approaching the permanent magnets nearer than $\frac{1}{4}$ of an inch (and what an enormous loss is incurred here!); with an engine constructed almost at haphazard, and with scarcely a consideration of the best principles or of the most advantageous construction of such engines, they actually obtained a result of 102·9 foot pounds out of a calculated theoretical maximum of 158. With a little care and consideration, I do not hesitate to say the duty per grain of zinc might easily have been increased tenfold." It is hardly credible, but the above looks very like a confusion between Force and Work! The author seems to assume that if the forces in operation in an engine are greater, that the engine will necessarily produce more work from the same quantity of fuel. In these experiments the quantity of zinc $(a-b)$ used to produce work W is observed; if the engine was made more powerful, if the permanent magnets were four times as strong, and the electromagnets passed $\frac{1}{8}$ of an inch from them, doubtless W would be greater, but so also would $(a-b)$, and it does not follow that $\frac{W}{(a-b)}$ with which we are concerned would be at all changed. What becomes then of the dogmatic assertion that the duty of a grain of zinc could be increased tenfold? Now let us turn to the paper in the *Quarterly Journal*. Here we may find enough in one article for our present purpose, taking chap. ii. art. 2,—"Why are we forced to suppose . . . . . . that the same amount of fuel produces the same amount of energy, whether it is consumed in the steam-engine, the horse . . . . . . the gnat? At any rate, we may observe that the very phrase is certainly a misnomer, and a misnomer of such a kind as to have a fatal effect in producing a false conception of things. For mechanical energy just as often produces cold as heat; it may produce either heat or cold, or neither. In fact, as a general rule, though with notable exceptions, every pushing or compressing force produces heat, and every pulling or expanding force cold. Place a weight on a pillar, and the weight produces heat in the pillar; hang it on a wire and it cools the wire. In exactly the same way, in a fire-syringe use force to press down the piston, it produces heat—heat enough to kindle tinder; but use the same force to pull up the piston, and it produces cold." Surely this is enough to show that the author's notions of what he is attacking are, to say the least of it, shallow; for what he quotes as paradoxes are simple deductions from the two laws of Thermodynamics. That a wire is cooled by stretching follows from the fact that heat expands it. In the case of the fire-syringe the case is simpler. The working body is the air in the syringe; on pulling up the piston this air does work, and therefore uses up heat and is cooled. Mr. Highton seems to imagine that because the arm of the experimenter does work, it is done *on the air in the syringe*, whereas this column of air and the observer are really co-workers in raising the air *external* to the cylinder. To point out all the fallacies of these papers in detail would take too much of your time. My object was to show that if the *Quarterly Journal of Science* and the *Chemical News* are to represent scientific opinion with any degree of truth, they would do well to use a little discretion as to what they print.—"Remarks on Mr. Spence's Experiments on the Effects of Cold on the strength of Cast Iron," by Joseph Baxendell, F.R.A.S. This was in reply to an assertion made by Mr. Spence the previous week that "he had so much confidence in the experiments then detailed, that he had no hesitation in giving it as an ascertained law that a specimen of cast iron having at 70° F. a given power of resistance to transverse strain will, on its temperature being reduced to zero, have that power increased by 3 per cent." Taking all the experiments on the effect of cold on iron which have yet been brought before the Society, they can only be regarded as indicating that if any effect at all is produced, it is more apparent on iron of good quality than on inferior iron, but that its amount is so small as to be wholly inadequate to account for the railway and other accidents which have been attributed to it.—"Further Observations on the Strength of Garden Nails," by J. P. Joule, F.R.S., &c. Since communicating the paper on the Alleged Influence of Cold in giving brittleness to Iron, I have collated the results with cast-iron nails in order to show the range of strength in such specimens:

Height of Fall of Hammer.	Percentage of Fractures.
2 inches	0
$2\frac{1}{2}$,,	0
3 ,,	6·25
$3\frac{1}{2}$,,	23·5
4 ,,	30
$4\frac{1}{2}$,,	36·4
$5\frac{1}{2}$,,	37·5
$6\frac{1}{2}$,,	48
7 ,,	65·5
$7\frac{1}{2}$,,	62·3
$8\frac{1}{2}$,,	75
10 ,,	92·8

I chose the garden nails for experiment after some thought, as presenting a marked variety of metal in contrast with the iron and steel wire, tempered and untempered. I did not expect them to possess great strength, but having found them to require a heavier blow than I expected to fracture them, I have had the curiosity to make some experiments on them which may be interesting to the Society. I took pairs of the nails, placed them head to point parallel to each other, so that pressure applied in the middle by pincers sufficiently forcibly would fracture one of them. Paper slips were pasted on the edges of the nails, and their distances asunder measured by a microscope with micrometer eyepiece divided by lines corresponding to $\frac{1}{800}$ of an inch. Weights were gradually added to the lever of one arm of the pincers until fracture took place, which was always accompanied with a sharp report. The observed deflection or bending of the nails was taken continuously as the weights were laid on, and the calculation of what it would have been at the moment of rupture taken from the immediately preceding observations. The amount of deflection was almost exactly proportional to the weight laid on in each experiment.

No. of Experiment.	Length of Nail between Supports.	Breadth of Nail in Fracture.	Depth of Nail at Fracture.	Deflection.	Breaking Weight. lbs.
1	1·05	0·13	0·127	·0062	145·5
2	1·1	0·114	0·125	·0067	141
3	1·1	0·120	0·115	·0090	171
4	1·08	0·111	0·106	·0073	142·5
5	1·12	0·122	0·145	·0098	189
6	1·06	0·138	0·120	·0087	184·5
7	1·08	0·150	0·118	·0095	201
Average	1·084	0·1264	0·1223	·0082	167·8

If we compare the above with Mr. Brockbank's experiments, we shall find, approximately, on reducing them to the dimensions he adopted, viz., three feet between supports and one inch section:—

	Breaking weight.	Deflection.
Mr. Brockbank's, with large bars...	860·7	·740
My own, with nails	2673·	1·106

The metal, in the form I used it, was therefore more than three times as strong as that of the large bars to resist a compressing and tensile force, while its extent of spring at the breaking weight was half as much again. Therefore, so far from being of inferior quality, it would sustain a very much heavier blow without fracture.—"On the Action of Sulphurous Acid on Phosphates," by Dr. B. W. Gerland.

Maidstone and Kent

Natural History and Philosophical Society, Feb. 20.—An aggregate meeting of the members of the Maidstone and Mid Kent Natural History Society was held at the Charles Museum, when Dr. Monckton, one of the vice-presidents, delivered a lecture on "The Metaphysics of Zoology."

Edinburgh

Royal Society, February 20.—Mr. W. F. Skene, V.P., in the chair. The following papers were communicated :—1. "On the Pentatonic character of Scottish Music," by the Hon. Lord Neaves. 2. "On the Motion of Solids in a Liquid," by Sir W. Thomson. 3. "Laboratory Notes on Thermo-electricity, and on Phyllotaxis," by Prof. Tait.

Paris

Academy of Sciences, January 27.—M. Janssen sent to the French Institute a letter to explain how his expedition failed, owing to the persistency of the clouds. He acknowledges fully the kind proposition of the Organising Committee to take steps to procure a *laissez-passer* from M. Bismarck on his behalf. In five hours M. Janssen proceeded from Paris to the mouth of the Loire, where he landed on the 2nd December at 11 o'clock in the forenoon. The journey was magnificent. M. Janssen travelled at a height of 1,100 metres at the beginning, but after sunrise his balloon elevated itself through the warmth of the sun, and he reached 2,000 metres without throwing out any ballast. M. Janssen has invented an instrument for helping aëronauts in the determination of their way along the earth. This contrivance, which was highly praised by M. Dumas, will be fully described.—M. Bazin presented a projectile gun which explodes in the air, where it is sent by a larger gun remaining on the ground. This projectile gun, when exploding at a certain point of the *trajectoire*, sends an explosive bullet with a new impulse. It is impossible to claim precision for such a projectile, which is called very properly *a double effect*, but the distance to which it reaches is increased, and the final bullet was sent to 7,919 metres, it appears with some effect. The experiment was tried against the Prussians during the last days of the siege.

February 21.—The sitting was very thinly attended by members. The public was more numerous. No scientific paper had yet resumed its publication. M. Faye presided over the sitting. M. Elie Beaumont and M. Dumas sat on the platform, reading over alternately the correspondence. An article on the "Duquesne" Expedition was sent by M. de Fonvielle. M. Elie de Beaumont, who had predicted that the "Duquesne" would go to Switzerland on account of its directing power, opposed the reading.—M. Stanislaus Meunier read a paper on the nature of meteorites, which, he thought, are evidently of astral nature. He is opposed to the theory of Schiaparelli, who accounted for them by supposing they are in some respects allied to comets.—M Chevreuil read over a letter from M. Vaillant, who hopes to be soon enabled to resume his seat.—M. Delaunay read the translation of a letter received from Prof. Piazzi Smyth, the director of the Observatory at Edinburgh. He noticed the admirable working of the International French Telegraphy. That service was transferred to Tours and from Tours to Bordeaux, where it is now working under M. Marié Davy's superintendence.—M. Ch. Saint Claire Deville reported that Dr. Berigny of Versailles had not interrupted for a single day his admirable series of observations kept regularly for 24 years. M. Renan, who is living at Vendôme, did not interrupt his observations, although he was several times arrested as a spy, but he was saved by his thermometer! The maximum of cold has reached $-16°$ at Montpellier, $-17°$ at Bordeaux, and $-3°$ at Perigueux. The winter was a sharp one. It was predicted by M. Renan, as belonging to a series of recurring sharp winters. This law of recurrence was published in *Comptes Rendus* eighteen months before war broke out.—News was circulated of other learned men amongst the members. M. Martillet remains at St. Germain as curator of the Prehistoric Museum. One new hall was opened during the Prussian occupation, the Prussian Emperor, Princes, and generals frequently visiting the galleries. M. de Verneuil has established himself at Duc de Broglie's castle in Normandy. He is a relative of the present French ambassador, who is very much interested in scientific matters. M. Janssen is at Bordeaux, and expected daily by his family.

DIARY

THURSDAY, March 9.

Royal Society, at 8 30.—Magnetic Observations made at Stonyhurst College Observatory, from 1863 to 1870: Rev. S. J. Perry.—Preliminary Notice on the Production of the Olefines from Paraffin by Distillation under Pressure: T. E. Thorpe and J. Young.—On the Action of Hydrobromic Acid on Codeia: Dr. C. R. A. Wright.
Society of Antiquaries, at 8.30.—On a probable allusion to the Chsritians in a passage of the Sixth Satire of Juvenal · Earl Stanhope, P.S.A.
London Mathematical Society, at 8.—Remarks on the Mathematical Classification of Physical Quantities: Dr. Clerk Maxwell, F.R.S.—On Skew Cubics: Prof. H. J. S. Smith, F.R.S.—Note on the History of Certain Formulæ in Spherical Trigonometry: I Todhunter, F.R.S
Royal Institution, at 3.—Davy's Discoveries: Dr. Odling.
London Institution, at 7.30.—On the Colonial Question: Prof. J. E. Thorold Rogers, M.A.

FRIDAY, March 10.

Royal Astronomical Society, at 8.
Quekett Microscopical Club, at 8.
Royal Institution, at 9.—The latest Scientific Researches in the Mediterranean and Straits of Gibraltar: Dr. W. B. Carpenter, F.R.S.
Royal College of Surgeons, at 4.—On the Teeth of Mammalia: Prof. Flower.

SATURDAY, March 11.

Royal School of Mines, at 8.—Geology: Dr. Cobbold, F.R.S. (Swiney Course.)
Royal Institution, at 3.—Spirit of the Age: Mr. O'Neil.

SUNDAY, March 5.

Sunday Lecture Society, at 3.30.—On Ferns: Dr. Cobbold, F.R.S.

MONDAY, March 13.

Royal Geographical Society, at 8.30.
London Institution, at 4.—On Astronomy: R. A. Proctor, F.R A.S. (Educational Course)
Royal College of Surgeons, at 4.—On the Teeth of Mammalia: Prof. Flower.

TUESDAY, March 14.

Photographic Society, at 8.
Royal Institution, at 3.—Nutrition of Animals: Dr. Foster.

WEDNESDAY, March 15.

Society of Arts, at 8.—On the Different Methods of Extracting Sugar from Beet-root and Cane: Ferdinand Kohn.
Meteorological Society, at 7.—Evaporation, Rainfall, and Elastic Force of Vapour: J. R. Mann.
Royal Society of Literature, at 8.30.
Royal College of Surgeons, at 4.—On the Teeth of Mammalia: Prof. Flower.

THURSDAY, March 16.

Royal Society, at 8.30.
Society of Antiquaries, at 8.30.
Royal Institution, at 3.—Davy's Discoveries: Dr. Odling.
Linnean Society, at 8.
Chemical Society, at 8.

NATURAL HISTORY MUSEUMS

THE notes upon Natural History Societies which have already appeared in these columns * would be very incomplete unless some reference were made in connection with them to the subject of local Museums. We would by no means have it inferred that a Museum should be looked upon as an essential adjunct to every local society; nor would we urge upon any such body the formation of a Museum, unless the society was in a position to warrant the supposition that, if once started, there would be every probability that it would be kept up; but, at the same time it must be admitted that a well-arranged collection of objects in connection with the more important of our Field-clubs, especially such as are far from London or some other centre, would be extremely useful.

But, to be of any service at all to working naturalists, a local Museum must be a very different sort of thing from the Museums with which those who have visited country towns are familiar. Of course, no reference is intended to such collections as those at Liverpool or Manchester; but to those smaller ones which might be made very useful, but are at present practically useless, of which that at Canterbury may be taken as a fair type. Here the jumble of curiosities and objects of natural history is (or was, when we visited it in 1867) sufficiently remarkable; and the want of arrangement yet more striking. Ancient pottery and various implements of savage warfare, pieces of the *Royal George*, and samples of the meaningless curiosities which are brought home by travellers to their friends and relations, and are often got rid of by the said friends and relations on the first opportunity—these are present in full force. There are also drawers of foreign insects, unnamed, and more or less damaged; some stuffed birds; a good many fossils, the labels of many of which are misplaced; a small collection of dried plants, rapidly succumbing to the ravages of insects; and various other objects. This is, as far as we can judge from experience, a fair example of a country Museum, certainly by no means the worst which we might have selected.

Such a state of things as this may be contrasted with the following description of what provincial Museums ought to be, which we extract from Dr. Hooker's Address to the British Association in 1868:—"Each should contain a connected series of specimens, illustrating the principal and some of the lesser divisions of the animal and vegetable kingdom, so disposed in well-lighted cases, that an inquiring observer might learn therefrom the principles upon which animals and plants are classified, the relations of their organs to one another, and to those of their allies, the functions of those organs, and other matters relating to their habits, uses, and place in the economy of Nature. Such an arrangement has not been carried out in any Museum known to me, though partially attained in that at Ipswich; it requires some space, many pictorial illustrations, magnified views of the smaller organs and their structure, and copious legible descriptive labels, and it should not contain a single specimen more than is wanted. The other requirements of a provincial museum are, complete collections of the plants and animals of the province, which should be kept entirely apart from the instructional series, and from everything else."

* See NATURE, vol. ii p 469, vol. iii. p. 161.

One of the most hopeful experiments in connection with the establishment of a local Museum, is that which has just been set on foot at Folkestone by the Natural History Society of that place. There has for several years been a Museum at Folkestone, although visitors to the town may not have been aware of it; the management, or mismanagement, of it was vested in a committee annually elected from the town council for that purpose; and until lately admission could only be obtained by an order from one of these functionaries. The Museum, when we visited it in 1867, contained a very valuable collection of fossils, chiefly local, including a fine set from the unique Junction Bed of Folkestone; a few birds and fishes, and one or two other objects, the whole thickly covered with dust, and in a disgraceful state of neglect. In 1868 the Committee of the Natural History Society offered to take charge of it, on condition that they might have the use of the room for meetings, &c., and this offer was accepted by the Town Council, subject to the agreement of the Committee to provide glass cases for the objects at their own expense. This they very properly refused to do, and matters remained thus until the election of a fresh Council, when the Society again applied. The Museum was ultimately placed in the charge of the Society, the Town Council providing fittings to the amount of fifty pounds, and an annual payment of ten pounds towards expenses. The objects were at once arranged and named, and the Museum was formally reopened on the 4th of last October. It is now opened to the public twice a week, the secretary, Mr. Ullyett, to whose exertions the improved state of affairs is mainly owing, being in attendance to give information if required. The meetings of the Society are held in the Museum. The aim of the Society is to make a complete local collection, as well as a type collection, on the plan suggested by Dr. Hooker as above quoted; and to this contributions are solicited. A library for reference is also in course of formation.

We have entered thus into detail because the history of the Folkestone Museum is by no means uninstructive, showing as it does how readily such local collections are allowed to become utterly useless; and how, in restoring such Museums to the use of the public, a local society is doing a good work which only such a body could perform the remonstrances of mere individuals being powerless in such matters. We should be glad if other Field-clubs having a Museum within the radius of their operations, would exert themselves in the same way; the East Kent Natural History Society, for example, might well reorganise the Canterbury Museum; and examples might easily be multiplied.

A Museum may be looked upon as especially useful in a school society; and we have already referred* to that existing at Marlborough as presenting very satisfactory features. Mr. Preston, who has worked so hard on behalf of this society, is anxious to establish a typical collection in addition to the British one, which has already attained considerable proportions. The series of botanical diagrams lately prepared for the Science and Art Depart-

* NATURE, vol. ii. p. 249.

ment at South Kensington, under the superintendence of Professor Oliver, will be valuable for such collections, so far as botany is concerned. The Museum at Clifton College, built by Mr. Perceval at a cost of 900*l.*, will, we understand, be confined to British objects, and will be a combination of Museum and Library.

In conclusion, it cannot be too strongly insisted that objects of *vertu* or of curiosity should be rigidly excluded from any Museum, be it large or small, which is ostensibly set apart for the illustration of Natural History. It may require a certain amount of firmness to draw the line, and so run the risk of offending good-natured persons by the rejection of their proffered help; but it is best to take at once a definite position, and, unless the space at command be much larger than is usual in local Museums, to refuse even objects of Natural Science which do not illustrate some typical peculiarity, or at the least tend to the completion of a provincial collection. It is better to have a few objects, well arranged, and each teaching some definite truth, than hundreds of disconnected specimens, which, however interesting in themselves, are valueless as aids to instruction.

SCIENCE IN VIENNA

IT is well to turn from time to time to what is doing in the cultivation of Science in other lands. We are able to give the following details of the progress of Science, or rather of the machinery for the cultivation of Science, in Vienna, from a letter addressed by Prof. Haidinger to Dr. E. Döll, the editor of the *Realschule*, in the December number of which periodical the letter appeared. It was written by Prof. Haidinger in commemoration of the establishment, on the 8th November, 1845, of the first Viennese association for the cultivation of pure science, the twenty-fifth anniversary of which the writer thought deserving of celebration even in the midst of the exciting events of the disastrous war then waging between two of the most advanced of European nations; events the results of which, as he justly remarks, do not constitute the highest objects of human life, but on the contrary, evils, originating only from our still imperfect civilisation.

Before the year 1845 it appears from this letter that the only scientific societies established in Vienna dealt solely with the applications of scientific knowledge. Thus the Imperial Agricultural Society was founded in 1807, with the warm interest of the late Archduke John. Its progress was interrupted by the war of 1809, and its statutes were not confirmed until 1812. In 1836 the Imperial Medical Society was founded, followed in 1837 by the Imperial Horticultural Society, and in 1839 by the Industrial Association of Lower Austria. Gatherings of German naturalists and medical men took place at Vienna in 1831, at Prague in 1837, and at Gratz in 1843.

In 1835 a step of the greatest importance was taken in the establishment of the Imperial Mineralogical Collection, which took the name of the Imperial Montanistic Museum in 1843. The instruction given at this institution was supplemented by the forms of a society.

In the year 1845, the period of the Industrial Exposition produced considerable excitement, and on the 8th of November in that year a number of young miners, medical men, and naturalists, met in the Museum, and established an association under the title of the "Friends of the Natural Sciences in Vienna." The list of those present at the first meeting includes the names of several men who have since risen to the highest reputation. Haidinger himself, then president of the Montanistic Museum, took the warmest interest in the success of the nascent society, and endeavoured to bring it into a perfect form, but, for some reason, without success. The meetings, however, were continued until the year 1850, and the subscriptions of the members enabled Prof. Haidinger to publish seven volumes of "Proceedings" in 8vo., and four volumes of "Memoirs" in 4to. The association was broken up after the foundation of the Imperial Geological Institute in 1849, and the library belonging to it was subsequently presented to that institution.

1846. The 30th of May is the date of the Imperial decree for the foundation of an Academy of Sciences in Vienna.

1847. On the 14th of May the statutes of the Imperial Academy of Sciences were promulgated, and the first forty members nominated. On the 29th of June the first functionaries of the Academy were nominated, and on the 2nd of December its first meeting took place.

1848. On the 2nd of February, the Imperial Academy of Sciences was solemnly opened by its curator, the Archduke John, and after this meeting the first part of the "Proceedings" was issued, forming the commencement of a long series of most important works in all branches of Science. The Academy of Sciences is not a society formed by the spontaneous action of its members, but rather an exclusive corporation founded by authority.

1848. On the 8th June, the Austrian Society of Engineers was founded, and is the first spontaneously-formed Society.

1849. The Imperial Geological Institute was established on the 15th November, under the Minister von Thinnfeld, on the foundation of the Montanistic Museum. This Institution partakes of the nature of a school of instruction, combined with that of a society.

1851. The 9th April witnessed the foundation of the first spontaneously-formed Natural History Society in Vienna, namely, the Zoologico-botanical Society, which owes its establishment to the exertions of Georg von Frauenfeld, who opened its first meeting on this day with an introductory address delivered in the hall of the museum of the Botanic Gardens. Frauenfeld was the first secretary of this society, a position which he still continues to hold.

1851. In this year also the Imperial Central Institute for Meteorology and Terrestrial Magnetism was founded under the direction of Karl Kreil, as a sequel to the labours of a Meteorological Committee of the Academy, appointed on the 18th January, 1849.

1853. The Antiquarian Society was formed under the presidency of Prince Aloys of Liechtenstein, on the 23rd March. On the 29th March, 1854, Dr. T. G. von Karajan was elected president. This is an independently-formed society.

1855. On the 1st December another independent society was established, namely, the Imperial Geographical Society, which held its first meeting on this day in the rooms of the Imperial Geological Institute. On this occasion the first president, Prof. Haidinger, delivered an address.

In the year 1856 much excitement was produced among the naturalists of Vienna by the meeting of German naturalists and physicians in that city, and a great impulse was given to Natural History studies by the voyage of circumnavigation performed in the years 1857-1859 by the frigate *Novara*, under the auspices of the Archduke Ferdinand Max, afterwards, to his misfortune, Emperor of Mexico. During this period also there was a movement in favour of publicity in the medical and philosophical faculties of the University, and some series of public lectures were delivered.

1860. On the 6th December the Society for the Diffusion of Physical Knowledge commenced its proceedings in the apartments of the Imperial Academy of Sciences. The first general meeting took place on the 13th May, 1861, in the hall of the Musical Society, when Prof. Eduard Suess delivered a foundation address. The proceedings and lectures may properly be carried back through the agency of Dr. J. Grailich and his associates to the year 1855, when they commenced in the meeting-room of the Imperial Geological Institute. This society has continued to give lectures on Natural Science in two places, in one of which the old forms of a society are retained, whilst in the other lectures find interested listeners.

1861. The Photographic Society, independently formed, held its first meeting under the presidency of Prof. A. Schrötter in the green saloon of the Imperial Academy of Sciences on the 22nd March. The first photographic Exhibition in Vienna was opened on the 17th May, 1864.

1862. The Austrian Alpine Club was established, its first constituent general meeting being held on the 19th November.

1864. The Lower-Austrian Society for "Landeskunde held its first constituent meeting on the 16th December.

1865. The Austrian Meteorological Society was founded on the 16th November, with an address from Dr. Karl Jelinek.

1866. The year of the war. Prof. Haidinger retired in consequence of ill health from the direction of the Imperial Geological Institute, and was succeeded by Franz von Hauer.

1869. A section of the German Alpine Association held its meeting in Vienna.

1870. The Chemico-physical Society established under the presidency of Prof. H. Hlasiwetz.

1870. The Anthropological Society founded on the 13th February. Its opening meeting was held in the Consistorial Hall of the University, when the president, Prof. Karl Rokitansky, delivered an address.

1870. The Numismatic Society established.

It is with a considerable pride that the venerable Prof. Haidinger describes the rapid advance that has been made in the scientific progress of his native city, and dwells upon the fact that the first impulse to this movement was given by the association of the "Friends of the Natural Sciences," in which he took so much interest. The cause of the failure to form a well-established society from such a promising commencement he finds in the unfavourable conditions of the time; and doubtless the spasmodic political movements which so closely followed the year 1845 may well have distracted the attention of German men of science. The nascent society seems, however, to have merged into the Imperial Geological Institute, which has already done so much good work, and Prof. Haidinger is probably in the right when he claims for the "Friends of the Natural Sciences" in their new capacity a vigorous influence in the establishment of other scientific societies both in and out of Vienna.

The 8th November, 1845, may therefore well be "a day of joyful commemoration" with Austrian scientific men, for although, as Prof. Haidinger remarks, any retrospect reaching so far back must bring with it serious thoughts of the many participators in the first labours of the period who have disappeared from the scene, there is yet a higher point of view of a satisfactory nature, namely, that this period of twenty-five years has raised Austria to a far higher scientific position among nations than could have been claimed for her before, and, as he says, "Peaceful progress is certainly the highest and worthiest object of human endeavours."

LAUGHTON'S PHYSICAL GEOGRAPHY

Physical Geography in its Relation to the Prevailing Winds and Currents. By John Knox Laughton, M.A., F.R.G.S., &c. (London: J. D. Potter, 1870.)

THIS work is designed to show that the whole atmosphere, relatively to the surface of the earth, continually moves or tends to move from west to east, and that the permanent local variations from this direction are either eddies or deflections, formed in accordance with the principles which regulate the motion of fluids (p. 312). In the course of the discussion, Mr. Laughton has done good service by showing that prevailing opinions respecting the circulation of the atmosphere are very far from being in accordance with many well-ascertained facts; and by insisting on the dependence of oceanic on atmospheric currents, which is confirmed in every case where the facts are tolerably well known. The book also contains the best popular account we have of the prevailing winds over large portions of the ocean. But he is not so happy with respect to prevailing winds over the land, and in the reasoning he employs in proof of a general motion of the atmosphere from west to east.

It is stated that from Japan northwards the prevailing winds in summer are westerly (p. 136); and to the influence of these winds, blowing across the northern opening of the narrow seas of this part of the earth, are ascribed the southerly winds on the coast of China, and thence southward to the equator (p. 280). Now the prevailing winds of this region are not westerly in summer, the direction being E.S.E. at Tong-chow, S.S.E. at Pekin and New-Chwang, S.S.W. at Nangasaki, S.E. by S. at Chacodate, E. at Nicolajewsk near the mouth of the Amoor, and N.E. at Ajansk, S.W. also prevailing to some extent at the last place.

We are told that the wind blows almost constantly from the west on the north-west coasts of the Old and New Worlds respectively (p. 154). Now, whilst in winter the prevailing wind in Vancouver Island is S.W., at Sitka it is E.S.E., easterly winds being to westerly as 4 to 1, and E.N.E. at Ikogmut. Again, over the whole of the west of Norway, the prevailing winds in winter are either S. or S.S.E. or S.E.; at Christiania they are N.E., easterly winds being to westerly as 8 to 3—a relation which could not hold if prevailing winds in this region were westerly. At Copenhagen the direction is S.S.W. In accordance with these facts the rainfall of the west of Scotland is much greater than that of the west of Norway.

Mr. Laughton maintains that there is, throughout the sea, no trace whatever of the air being drawn in to any place of greatest heat, &c. (p. 303), and adduces many instances in support of this opinion; but, curiously enough, every case adduced confirms the opposite view. This arises from a misapprehension of the principle involved in Buys Ballot's Law of the Winds, which may be thus put: Winds flow in towards the space where pressure is weak, vorticosely, so that in the N. hemisphere, standing back to the wind, the weak pressure is to the left. To take one case as an illustration:—Because the winds at Aden and south of Arabia do not blow directly in upon the heated sands of that region, but blow from W.S.W., it is concluded that there is no trace whatever in this part of the sea of the heated air influencing the winds. Now, if it be the case that there is at this season a weakening of the pressure by an ascending current of heated air from the surface of Arabia, then, according to Buys Ballot's law, the direction of the wind ought to be what observation shows it is, viz. W.S.W., and the more powerful the ascending current, the stronger will be the W.S.W. winds on the surface.

Mr. Laughton regards it as established presumptively that a westerly upper current everywhere prevails (p. 97). This he has shown generally to be the case as respects upper currents of tropical regions and a portion of the United States, but not as respects other parts of the globe. The explanation of these upper currents is easy. If the pressure of the atmosphere, at a uniform height of say, 10,000 feet, were ascertained, the highest would be immediately over the belt of calms, and the lowest over those regions where the mean temperature of the whole stratum, 10,000 feet thick, happens to be the lowest; this result being a simple consequence of the increased tension of air by heat, and diminished tension by cold. Since the pressure at the height supposed will continually diminish on receding from the Equator on either hand, it follows from Buys Ballot's Law that the prevailing upper currents ought to be westerly within the tropics, or, stated more exactly, W. by S. north of the Equator, and W. by N. south of it. It is during the winter months that westerly upper currents prevail in the United States. Since during this season the mean temperature rapidly sinks in advancing northwards over America, atmospheric pressure will be much weaker over British America at a height of 10,000 feet than over the United States, and hence by Buys Ballot's Law the upper current of the United States ought to be westerly. It may be remarked that since westerly upper currents are flowing towards colder regions, condensation of their vapour into cloud must frequently take place, thus rendering them visible; whereas since easterly currents flow towards warmer regions, condensation will seldom take place, and hence they must frequently flow past unobserved.

The broad zone included between latitudes 30° N. and S. comprises half the superfices of the globe. Over by far the greater portion of this zone winds are easterly, there being no season when any approach to a preponderance of westerly winds is apparent. When to these are added the easterly winds in extra-tropical regions, already referred to, a predominance of easterly winds in the north of Siberia and in the east of Australia, in their respective summers, and in a large part of the Arctic regions at all seasons; and though not a predominance yet the frequent occurrence, of easterly winds in the S. hemisphere, south of latitude 50°, it is plain that if there can be a preponderance of westerly winds over the globe viewed as a whole, it cannot be very great. A. B.

THE SEWAGE QUESTION

The Practical Solution of the Great Sewage Question, by a Combination of the Irrigation and Precipitating Processes. By William Justyne. (John B. Day.)

IN this little book the author tries to show that the A B C process is the only one which promises any hope of success among the methods which have been proposed or adopted for purifying sewage and utilising its valuable manurial constituents. "Miscellaneous schemes," including the dry-earth system, Liernur's process, and all the precipitation plans, except the favoured one, are dismissed very summarily, and the irrigation system is made to look as unsuccessful and as dangerous as its opponents have ever represented it to be, while the immense weight of indubitable facts and evidence on the other side is entirely passed over.

Then the A B C process is minutely described, and the scientific public is asked to believe that sewage, which contains suspended and dissolved organic and inorganic matters, and the chief value of which consists in the large amount of dissolved nitrogen, especially in *the form of ammonia*, which it contains, can be so purified by precipitation with a mixture of alum, blood, clay, animal charcoal, and what not, as that the effluent water shall contain no putrescible matter, and that the *precipitate* shall contain the manurial constituents!

What we do know with regard to the A B C and all other precipitating processes is, that they none of them separate out anything like all the dissolved (few of them nearly all the suspended) organic matters, and that the ammonia is necessarily all lost in the effluent water; indeed, several of these processes have been known actually to increase the amount of ammonia in the effluent water, by decomposing some of the organic matters. The only precipitating process which had the merit of attempting to throw down the ammonia was the phosphate process, which has been tried and abandoned so many times in this and other countries; the reason of its failure was very simple: the ammonio-magnesian phosphate which it was expected would be found in the precipitate, requires an excess of ammonia in the solution to render it at all insoluble, so that if any of this salt were contained in the sediment it would merely show that the effluent water still contained an excess of ammonia.

We must comment especially upon two points in which a person seeking for information is likely to be misled as to matters of fact by consulting this book. On page 17 we observe a table of the average percentage composition of solid and fluid human excreta, from which one might easily be led to suppose that the solid is more valuable than the fluid (as it is *weight for weight*), but we nowhere find the important fact added that since for every ounce of solid excreta we have about 10 ounces of liquid, the total liquid excreted in a given time is worth about seven times as much as the total solid: so that as far as utilisation is concerned, the question which has to be solved is, how to deal with the liquid and its valuable constituent urea, or rather carbonate of ammonia, for it is as such that we find it in sewage.

The other point is the statement at the bottom of page 56, that "the analysis of the effluent water, after the sewage has been treated by the A B C process, is an analysis of the effluent water *solely;* whereas in almost every case where analyses have been made of the effluent water after the irrigation process, the effluent water has been diluted by at least double and sometimes three and four times its bulk, with perfectly pure spring and subsoil water." But then, how is it that the effluent water is, except during very wet weather, so very much less in quantity than the sewage sent on to the land? Mr. Justyne does not tell us this—we will tell him; it is because three-fourths, sometimes four-fifths, sometimes much more of the water has disappeared by evaporation from the leaves of the growing plants, and to a certain extent from the surface of the ground itself, so that to compare fairly the composition of the effluent water of the A B C process with that of an irrigated field, we must dilute the latter with distilled water until its bulk is equal to that of the sewage sent on to the land; even without this correction, the purity of the effluent water from irrigated lands has never been approached by any other method; with this correction, we think we may safely say that it is never likely to be approached.

Our author suggests that irrigation with the effluent water should be practised, when necessary, as a secondary and subordinate operation to the precipitation process; we submit that it has never yet been shown that it would not always be necessary to irrigate with this effluent water, both from a sanitary and an economical point of view, and it is plain that if to purify sewage, irrigation must be resorted to, any preliminary process which separates more than the offensive suspended matters, must be disadvantageous, by lessening the value of the liquid sent on to the land.

That the suspended matters should be to a great extent separated before the sewage is sent on to the land, we hold to be indisputable, but this should be done by some simple method, which leaves the sewage as *rich as possible* in dissolved manurial constituents.

In conclusion, from a chemical point of view, we object to reliance being placed on any precipitation process for the removal of its valuable constituents from sewage, and from a sanitary point of view we object to the effluent water from precipitation tanks being sent at pleasure into streams whose water is afterwards used for domestic purposes.

W. H. C.

OUR BOOK SHELF

The Honey Bee; its Natural History, Physiology, and Management. By Edward Bevan, M.D. Revised, Enlarged, and Illustrated by William Augustus Munn, F.R.H.S., &c. (Van Voorst, 1870.)

In this new edition of Dr. Bevan's well known work, Major Munn has given a full account of all the improved hives and methods of management, and of the most recent discoveries in the economy and physiology of bees. The old and the new matter are, however, so interwoven, that it is impossible for the reader to separate them; and as the original author and his editor both speak in the first person, we find ourselves continually at a loss to know whether we are reading "Bevan" or "Munn," except in those cases where some reference to dates enables us to decide.

An interesting experiment is detailed, proving that the business of a hive may go on a long time with perfect regularity without the presence of a queen. On the 13th June a swarm was put into a mirror hive. On July 1st, whilst the queen was laying drone eggs, she was taken away, yet the bees showed no agitation, but continued their work as usual. They formed several royal cells, and examined them continually to see if eggs had been deposited in them. All through the summer work went on as usual, honey being plentifully stored; but no attempt was made to raise a queen by artificial food, nor were the drones massacred. By the middle of November all the drones had died, and the working bees then began to diminish, and by December 31st they had also died. As all the workers had been born before July 25th, this gives about six months, or not much less, for the duration of their lives.

The fortifications and barricades of the bees against the incursions of the Death's Head Moth are said to be due to reason rather than to instinct, because it has been observed that they do not commence these fortifications on a first attack of the Sphinx, nor until they have been robbed of nearly their whole stock of honey. "This is a case in which the insect is taught by experience, and which admits, in all its particulars, of a direct comparison with human reason and contrivance. A colony that had been thus attacked one year, and was tardy in its defensive operations, having derived instruction from the past, constructed fresh ramparts speedily on the reappearance of the Sphinx three years afterwards, and thus guarded itself from an impending danger. Since the lives of the working bees do not extend beyond six or seven months, it is evident that the information of the colony above referred to must have been traditional, or else derived from a queen which had reigned over them three years previously." This "tradition" through some six or seven generations seems highly improbable, and that the knowledge of how to act was derived from a queen not less so. Do not the facts rather indicate that bees differ considerably in intellectual capacity, and that some hives contain directing bees more capable of acting promptly on the defensive than others?

Much information is given on the different kinds of foreign bees, and their peculiar modes of building. The importance of bees in fertilising flowers, and the use of nectar and of the colours of flowers as attractions, are fully recognised; but the recent discoveries of Darwin on this subject are not alluded to. So, in the discussion on the hexagonal form of the cell, the "circular" theory is opposed, and Mr. F. Smith is quoted against it; but the beautiful experiments of Mr. Darwin, as described in the "Origin of Species," with the satisfactory theory founded upon them, appear to be unknown to the author. "Darwin," it is true, is very frequently quoted, but it is always Doctor, not Charles, Darwin.

The book is illustrated by woodcuts of the various kinds of hives, and of the apparatus used by Apiarians. There are also some very scratchy but characteristic etchings of the different kinds of bees and of their anatomy, and several coarse coloured lithographs of varieties of comb, royal cells, &c., all executed by Major Munn himself. Though with some deficiencies of style and arrangement, the work abounds with information useful to the bee-keeper, and interesting to the naturalist.

ALFRED R. WALLACE

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.]

Eozoön Canadense

I CANNOT understand Mr. T. Mellard Reade's right to fling the taunt at those who maintain the foraminiferal nature of Eozoön, that "each disputant takes up a different position, and shifts it as occasion requires."

I have never taken up any other position than this: that *the best-preserved specimens of the Canadian Eozoön exhibit an unquestionably foraminiferal structure.* I am supported in this by every British naturalist with whom I am acquainted, as specially conversant with foraminiferal organisation, viz., by Messrs. H. B. Brady, T. Rupert Jones, W. K. Parker, and Prof. W. C. Williamson; whilst the most eminent authorities in micro-mineralogy and pseudomorphic structure, viz., Messrs. David Forbes, T. Sterry Hunt, and H. Sorby, altogether disown Eozoön as a mineral.

I have further asserted, and I do not in the least "shift" my position, that *the character of the Canadian Eozoön is altogether independent of that of later ophites.* The occurrence of true Eozoic structure in the newest Tertiaries would only show that Eozoön, like Lingula, has maintained its continuity through a long succession of geological epochs. On the other hand, the occurrence of minerals presenting superficial resemblances to true Eozoönal structure, can be of no account to such as really understand the latter.

If the Skye ophite, for example, possesses a true "nummuline layer" in combination with other characteristic Eozoönal features, its presence in a formation of later "geological time than the Laurentian," furnishes no argument whatever against its organic character.

If, on the other hand, the supposed "nummuline layer" in the Skye ophite is nothing but a lamella of chrysotile, the existence of such a pseudomorph can only affect the opinions of such as are incompetent to distinguish the two by those microscopic tests on which experienced observers feel perfect reliance.

Since I do not feel called upon to expend valuable time in giving to Mr. T. Mellard Reade the instruction which he requires to qualify him for discussing this question, I now leave him to the enjoyment of his own opinion. Whenever he shall have shown, by work of his own, his competence to criticise the observations of others who have made a special study of the subject he discussed, I shall be most happy to afford him the same opportunity of forming his judgment as to the organic nature of Eozoön, by an examination of my preparations, that I have given to the many eminent naturalists, who have thus fully satisfied themselves of the justice of my conclusions.

W. B. CARPENTER

Dr. John Hopkinson on "The Overthrow of the Science of Electro-Dynamics"

As I see you have reprinted at length Dr. Hopkinson's paper with the above title, in which he criticises severely, not to say ungenerously, some papers of mine published in the *Quarterly Journal of Science* and *Chemical News*, you will think it only fair to publish my reply, in which I think I shall show that, in the course of his short paper, Dr. Hopkinson has committed mistakes at least as grave and important as any he imputes to me. Let us see if this is not the case.

Dr. Hopkinson quotes one of my articles as follows: "They (that is Joule and Scoresby) calculate the maximum theoretical power of a grain of zinc to be 158 foot-pounds, and yet using permanent magnets, which, by their own statement, were so badly constructed as to have only a quarter the power they ought to have had, with the poles of the electromagnets never approaching the permanent magnets nearer than $\frac{1}{4}$ of an inch (and what an enormous loss is incurred here!); with an engine constructed almost at haphazard, and with scarcely a consideration of the best principles or of the most advantageous construction of such engines, they actually obtained a result of 102·9 foot-pounds out of a calculated theoretical maximum of 158. With a little care and consideration, I do not hesitate to say the duty per grain of zinc might easily have been increased tenfold." On which he observes, "It is hardly credible, but the above looks very like a confusion between Force and Work! The author seems to assume that if the forces in operation in an engine are greater, that the engine will necessarily produce more work from the same quantity of fuel. In these experiments the quantity of zinc $(a-b)$ used to produce work W is observed; if the engine was made more powerful, if the permanent magnets were four times as strong, and the electromagnets passed $\frac{1}{8}$ of an inch from them, doubtless W would be greater, but so also would $(a-b)$, and it does not follow that $\frac{W}{(a-b)}$, with which we are concerned, would be at all changed. What becomes, then, of the dogmatic assertion that the duty of a grain of zinc would be increased tenfold?"

Why he should say, "It is hardly credible, but the above looks very like a confusion between Force and Work," I know not. I cannot plead guilty to having made the slightest confusion between the two. I do think the total of the force used is *a measure* of the work produced. But Dr. Hopkinson tries to persuade us that a well-constructed engine would do no more duty than an ill-constructed one, and consequently, I presume, that the magnets might possibly be weakened *ad infinitum*, and removed to ever so great a distance, without necessarily affecting the efficiency of the engine. And then he ventures to criticise my papers as full of fallacies! I retort that it is hardly credible, but that the above looks very like a confusion between $(a-b)$ and b! In these experiments of Joule and Scoresby's the quantity of zinc used to produce work W, is represented by the authors not as $(a-b)$ but as b, and therefore the duty per grain of zinc is not $\frac{W}{a-b}$ but $\frac{W}{b}$; and when the permanent magnets are stronger, and the electromagnets are passed nearer to them, not only does W increase but b also diminishes. So that was I not justified in saying that the duty of a grain of zinc could in a better-constructed engine be probably increased tenfold? And if it be increased only twofold, or even half as much again, then, allowing for waste, I have proved my point, and disproved Joule's mechanical equivalent of heat. Might I not retort fairly on Dr. Hopkinson that the Manchester Literary and Philosophical Society "never ought to have permitted this paper to appear in their Proceedings?"

Next let us take Dr. Hopkinson's next criticism. My argument is this:—That if the doctrine of the mechanical equivalence of heat be, *that production of energy absorbs, and destruction of energy produces, a definite amount of heat*, and if we find cases, as those of elastic wires, and water below its maximum density, in which destruction of energy produces cold, not heat, the doctrine of the mechanical equivalent of heat cannot be universally true. To this argument Dr. Hopkinson replies that the facts I quote as paradoxes are simple deductions from the two laws of thermo-dynamics. Quite true; but this only shows that one of the laws of thermo-dynamics is inconsistent with the doctrine of the mechanical equivalence of heat. Might I not retort again on Dr. Hopkinson that "a hostile critic should at least understand the meaning of what he criticises"?

If I said anything which *seemed* to imply that a minimum of work in an engine was inconsistent with a maximum of duty, I freely retract the expression; and I also acknowledge that the argument drawn from the fire-syringe had better have been omitted. But my point was proved abundantly without it.

But still, as the maximum of work done by a battery before it is worn out is only a multiple of the maximum duty of a grain of zinc, I do think it is a *startling* thing, though not mathematically impossible, that this maximum of work should prove to be no work at all.

Perhaps you will allow me to add that I have read Sir W. Thomson's paper read before the British Association in 1852, to which your own reviewer referred me. No doubt you will think it presumptuous in me to say so, but I think that in that paper he has mixed up two totally distinct questions, namely, the cold produced by the decomposition of water into its elements at two electrodes, and the heat produced by the resistance of the film of hydrogen or oxygen or oxide, to the passage of the current. The first is a fixed determinate quantity; the second an accidental one depending on the character of the surface of the electrode, and the ease with which it throws off the film of hydrogen or oxygen. These two points affect the question, as well as the polarisation, and the specific power of retaining or transmitting heat exercised by various electro-motive combinations. M. Favre suggests the formation, sometimes, of peroxide of hydrogen; but this supposition is unnecessary, and, moreover, would not remove the difficulty, for peroxide of hydrogen is so unstable a compound, that it would soon be resolved into oxygen and water, and thus exactly undo the thermal effect of its formation. I trust that in this letter, at least, you will find nothing unfit to be published in a scientific journal.

H. HIGHTON

P.S. I hope to discuss the question *vivâ voce* at the meeting of the Manchester Literary and Philosophical Society next week.

MR. HIGHTON has very effectively shown the uselessness (to him) of my review of his speculations. I wish I could withdraw it, and allow his letter to speak for him without any comments of mine. When a man can make the remarks he has made on Sir W. Thomson's paper of 1854, his case is hopeless—he is incapable of being taught even by the "grand founders" of the science. *Requiescat.*

YOUR REVIEWER

Quinary Music

HAVING hitherto been under the impression that all the varieties of time in music might be regarded as made up of groups of two or three, and never having seen a single piece of music which in any way contradicted this view, Mr. J. Mullen's letter on "Quinary Music" in NATURE for the 9th inst. surprised me very much indeed. It is true that sometimes we meet with passages in which five notes are to be played in the time of four, or seven in six, &c.; but a piece of music in five time is a thing I at least have yet to see, and I should feel obliged to Mr. Mullen it he will kindly tell me the name and composer's name of this novelty.

BEACON LOUGH

The Experimental and Natural Sciences in Trinity College, Dublin

I TRUST you will allow me to make a few remarks upon the article signed "W." which appeared in your last week's number.

In the first place, there are one or two inaccuracies which may be corrected. Thus, your correspondent states that a student "in his third and fourth years *must* devote himself, to a certain extent, to the study of Experimental Physics, including heat, electricity, magnetism, and chemistry, and pass examinations on these subjects, even at the ordinary term examinations." The sophister students are indeed *allowed* by the Board to substitute such a course for classics, but, it may be added, comparatively very few avail themselves of this permission. Again, it is declared that "the chemical and physical laboratories leave nothing to be desired." No such thing as a "physical laboratory" exists in the University; and, seeing that it is only lately that such things have been introduced at the other side of the Channel, it is scarcely likely that we shall have one here for some years to come.

But what I think especially calls for criticism is the general tone of the article, leading the reader, as it appears to me, to suppose that the Experimental and Natural Sciences occupy a high status in Trinity College, Dublin. Now this is far from being the case; there can be no doubt that they are still generally looked upon in the University as subjects of quite secondary importance.

A.

Dublin, March 14

Science in Schools

I SHOULD be greatly obliged if you would kindly let me know of any school adapted for young boys whose parents wish to give them an education embracing the physical sciences and modern languages, on some such plan as that of the Realschule of Germany.

W.

Dr. Donkin's Natural History of the Diatomaceæ

THE remarks of "K." on my review of the above-named work (*vide* NATURE, vol. iii. p. 348) fall under five heads. Allow me to briefly notice each. 1. There is a difference of opinion between us as to the execution of the plates in Part 1 of Dr. Donkin's work; my copy came direct from the publishing office, it is therefore presumably a fair specimen. I have once more examined the plates, as well as shown them to several competent judges, and the unanimous verdict of all is that expressed in my notice, *i.e.* the execution of the plates in this part is disappointing. I gave instances of apparent inaccuracy in detail in some of the figures. "K." passes these by, but cites figures that are accurate; surely there is nothing contradictory in this. My criticism related for the most part to the *execution* of the plates, and I confess that even comparing them to those illustrating Dr. Donkin's or Mr. O'Meara's papers on Diatoms in some of the late volumes of the *Quart. Journ. Micr. Sci.*, I would prefer the lithographic plates to the engraved ones.

2. "K." agrees with me about the synonymy. I agree with him as to the difficulty of this portion of the subject, but what value would this or any work on species have without synonyms?

3. "K." says the desirability of giving habitats in full is questionable, "three or four localities are sufficient." Unquestionably it is not desirable to give more than three or four localities for common forms, but I think it is equally unquestionable that when Dr. Donkin could have given as many localities for interesting and not extremely common forms, he was wrong not to have done so; and I alluded to the absence of Irish localities in the hope of removing an evident defect in an otherwise useful work.

4. "K." is, without doubt, right in referring the species given by him to Gregory, and not to Ehrenberg. I cannot imagine how so great a blunder on my part originated.

5. "K." asks, "who is Cleeve?" Cleve (not Cleeve), next to Heiberg of Copenhagen, is one of the best northern investigators of the lower Algæ. His monograph of the Swedish species of the Zygnemaceæ is well known, and in addition to his papers on Desmideæ and Oedogonium, he has published "Diatomaceer fran Spetsbergen" (1867) and "Svenska och Norska Diatomaceer" (1868). He naturally follows the arrangement of the "Conspect. Crit. Diatom. Danicarum." It is not without interest to observe how well acquainted these botanists are with the literature in our language relating to the Diatomaceæ.

W.

Lenses for Vision Below Water

IN a communication on the Dioptrics of Vision which appeared in your impression of the 15th December last, I described a form of air-lens for vision beneath the water. Further experience has shown me that the measurements I then gave were not so accurate as they might have been. Thus, the radius of curvature of the glasses in the air-lens to form a lens with a 2 in. focus in water is not $1\frac{1}{4}$ in. as first stated, but 1 in. only.

Again, I somewhat underestimated the magnifying power of the anterior lens of our eye, formed by the aqueous humour, when I set it down as a lens with a focus of 2 inches. $1\frac{1}{2}$ inch is more correct. In accordance with this, I find that for the most perfect vision under water, we require a glass lens of $\frac{5}{8}$ in. focus in air (in place of 1 in. as formerly stated), or an air-lens formed with two segments of a hollow glass globe $1\frac{3}{4}$ in. in diameter, placed concavities outwards. Both these lenses have in water a focus $1\frac{1}{2}$ in. long.

These lenses are for fresh water. Sea water having a greater refractive power than fresh water, requires for perfect vision a somewhat *more convex* glass-lens and a somewhat *less concave* air-lens. I find that an air-lens made with segments of two glass globes of the diameter of 2 inches and $1\frac{3}{4}$ inches respectively, when immersed in sea water forms a lens of $1\frac{1}{2}$ in. focus. But I should observe that good vision under water is obtained by lenses of various magnifying powers, ranging from $1\frac{1}{2}$ to 2 inches focus; but for the distinct vision of small text-type under water, the higher magnifying power is required, and it also is the best for distant vision under water.

53, Montagu Square

R. E. DUDGEON

Petrography

THE few English geologists who take an interest in petrography will be thankful to Mr. Geikie for the communications from him which have appeared in NATURE. It is too true, as he observes, that our progress in this branch of geology has for many years been simply *nil*, but there are now manifest signs that this unsatisfactory state of things is drawing to a close. Some of our working geologists are quite aware of the necessity which exists for the application of the microscope to the examination of rocks, and they do not doubt that the result will be proportionately as great as it has been in other branches of inquiry.

It may in the first place be observed that the unsatisfactory nomenclature at present in use is due to the fact that a considerable proportion of the igneous rocks have been named without any precise knowledge of their mineralogical composition, mere chemical analysis being quite inadequate for the solution of the problem; and now there is an evident tendency towards the partial adoption of a chronological classification, founded, no doubt, on the prevailing belief in an essential difference between the "plutonic" and "volcanic" rocks, and on the notion that the age of such rocks may be determined by their mineral constituents, just as sedimentary deposits may be recognised by their included fossils. The microscopical examination of many hundred thin sections of the older melaphyres and more recent basalts establishes the fact that no such essential difference exists, but that, on the contrary, the same minerals are the constituents of both; a difference there undoubtedly is, but the microscope shows that it has been produced by chemical action operating under more or less favourable circumstances during long periods of time. Numerous specimens of the so-called melaphyres from the coal-fields of Scotland and the midland counties are unquestionably composed of the same constituent minerals as the tertiary basalts from the coast of Antrim, Auvergne, and the Rhine.

On comparing the least altered portions of the older rocks with some of the basalts, no difference whatever is observable; triclinic felspar, magnetic oxide of iron, augite, and olivine are the chief ingredients of both. The latter mineral has been regarded as characteristic of the more recent basalts, but, as I have shown elsewhere,* it exists quite as frequently in the melaphyres.

The fact, however, on which it is most important to insist, and which has not hitherto been recognised, is that the difference now existing between old melaphyres and recent basalts is due to chemical action subsequently to the formation of the rocks; not only have most of the amygdaloids been thus formed, and numerous microscopic cavities filled up, but the felspar is frequently much altered, and pseudomorphs of olivine, augite, and hornblende have been formed; thus producing a marked change in the colour and hardness of the rock. Pseudomorphs of olivine are the most abundant, and are of great interest, as crystals in various stages of alteration may frequently be observed.

Prof. Zirkel has shown that in some basalts the various constituents have crystallised firmly together, and lie in actual contact with each other without any intervening cement, while in other cases there is an amorphous glassy substance in which they are embedded. Precisely the same facts may be observed in many melaphyres, and notably so in some of the rocks from the Glasgow coal-field. Many of these rocks from the Scottish carboniferous strata are of great importance in these investigations, as their age has been satisfactorily determined by the valuable labours of Mr. Geikie and his brother.

In revising the nomenclature, it will be for petrologists to decide whether or not two rocks originally of identical composition should receive different names because one has undergone a certain amount of alteration. In most cases there is undoubtedly a difference in their appearance, and it might be convenient to recognise the fact in the nomenclature; but Mr. Geikie's anticipation that "there is such an insensible gradation that no sharp line can be drawn between them" will certainly have to be recognised.

If this method of microscopical analysis is carefully carried out on a sufficiently extensive scale, there can hardly be a doubt that we shall soon acquire a more satisfactory knowledge of all the older rocks; some little has already been done with the melaphyres, and I hope shortly to submit the results to the judgment of those interested in the subject. S. ALLPORT

Tin

THE discussion of the isolation of St. Michael's Mount subject has now branched off into a subsidiary question, which should not pass unnoticed. A writer dwelling on the abundance of tin found in Britain, argues that this natural product of our soil has given a name to our island home. I have met with this suggestion elsewhere, but have never been able to accept it. Our word *tin* is of comparatively modern formation. The Welsh word is *ystaen*, which corresponds so closely with the Latin *stannum* as to lead to the inference that the one form is derived from the other, although we may not be able precisely to say which is the elder of the two.

Now, all things being equal, our modern word *tin* might be accepted as a corruption of either of the above forms; but that it really is more nearly allied to the Teutonic forms of the same word, as found in Saxon, Danish, German, Swedish, &c., all being equally traced to a primitive root preserved in the Sanscrit word *tan*.

It will thus appear almost certain that our word *tin* is of Teutonic origin, and not used in this island so early as the argument for its forming a particle of the word Britain requires. My objection being thus stated, that the word *tin* is a comparatively modern word with us, if of Teutonic origin; yet, on the other hand, if it be assumed as a plausible corruption of the Welsh *ystaen*, or the Latin *stannum*, it appears to me that the primitive words for Britain ought to be found spelt in such variety of form as to lend some countenance to this idea, if it be really founded on fact. But it is not so; consequently we must not indulge the fancy that that useful metal "tin" has any place in the construction of the word Britain. A. H.

PAPERS ON IRON AND STEEL

No. III.—The Bessemer Process*—(*continued*)

RETURNING to the Bessemer flame, we now reach what I have described as its second stage, when its dimensions and brilliancy reach their maxima. We know that carbon must be burning there, and in no small quantity. The average of above three per cent. shown in the analyses, gives in a charge of six tons more than 3·6 cwt. of carbon, requiring for its complete combustion into carbonic acid nearly half a ton of oxygen, or about two tons of atmospheric air. There need be a mighty roar to pour forth all this, and the 14cwt. required for the silicon in the course of about twenty minutes. An interesting problem now presents itself in the whiteness and brilliancy of the flame. It is totally different from the carbonic oxide flame which is produced by the combustion of carbon *per se*. Whence comes this whiteness? Is it due to the combustion of iron in addition to that of carbon, to solid particles of carbon, or is there any important quantity of hydro-carbon present?† The latter explanation is forcibly suggested by the appearance of the flame, and is, I think, to some extent, confirmed by the spectroscope. There is still, however, some red smoke above the flame, which, though less abundant now than in some other stages of the blow, is sufficient to indicate that some iron is burning, probably small particles mechanically ejected into the flame by the force of the blast.

It is during this period of the blow that the lines which have been figured and described by Dr. Watts and Dr. Roscoe as the spectrum of the Bessemer flame are most distinctly displayed. This spectrum includes some of the iron lines, the lines of lithium,‡ sodium, and potassium, and the red band of hydrogen seen as a black band, besides the very complex series of lines which have been designated "the carbon lines" of the Bessemer flame. These lines probably include a hydro-carbon spectrum,—I say "probably," because they do not exactly correspond with the hydro-carbon spectra with which they have already been compared. Nitrogen lines are also displayed, but whether these are due to cyanogen, or to any other compound including carbon and nitrogen, has not yet been determined. What then is the particular compound of carbon which is burning in the Bessemer flame? Is it a hydro carbon, and if so, with which of the many known varieties of hydro-carbon does it correspond? Do the nitrogen lines belong to any compound of nitrogen whose spectrum may be identified?

These are questions of considerable philosophical and practical interest which, I think, the spectroscope may be made to answer. Hitherto, the spectroscopic investigations

* We regret that, owing to the pressure on our space, we have been compelled to keep this article, and the one printed last week, in type for some weeks; similar conclusions have in the meantime been arrived at by other observers.—ED.

† I speak of solid particles of carbon as quite a distinct case from hydro-carbon flame, believing in the soundness of Frankland's conclusion that the brilliancy of a hydro-carbon flame is *not* due to the combustion of solid particles of carbon. My own experiments on the transparency of the *white portion* of common coal gas flames strongly confirm Dr. Frankland's view.

‡ I have only found the lithium occasionally. In many instances I have watched a blow from beginning to end without observing any appearance of the red lithium band which, when seen at all, is so unmistakeably brilliant.

of the Bessemer flame, though skilfully and laboriously conducted, have been curiously barren of philosophical results, and for practical purposes altogether a failure. If the above questions were answered it would be different.

During the first part of the blow a large proportion of the graphitic carbon of the grey iron becomes converted into the condition of "combined carbon" such as exists

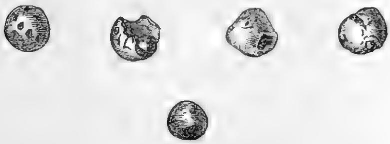

FIG. 1.—"BOMBS" PRODUCED IN THE BESSEMER PROCESS.

in steel and white cast-iron. What then is the condition of this carbon if it yields a cyanogen or hydro-carbon spectrum? Nitrogen has been found in considerable quantities in cast-iron which is rich in carbon. Steel makers know that organic compounds containing nitrogen as well as carbon are far more efficacious in cementation than carbon in a state of comparative purity. Thus, bone dust is more effectual for case-hardening than wood charcoal, and ferrocyanide of potassium still more effectual than bone dust. Every steel maker is the proud possessor of a profound secret, a "physic" which he furtively buys from a distant druggist or drysalter, and having disguised its yellow colour by grinding it with lamp black, locks the physic in a strong box and the secret in his own bosom. As this profound secret, like so many others, is perfectly well known to all whom it may concern, I perpetrate no breach of confidence in describing the "physic" as the ferrocyanide of potassium. Its value is unquestionable, but *how* it acts is still a mystery.

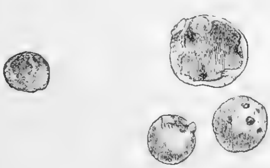

FIG. 2.

Some chemists have maintained that a nitride of iron is essential to the production of steel, and others have hinted at the existence of a cyanuret. As we know that carbon exists in the same condition in white iron as in steel, a question of considerable interest is offered for spectroscopic solution, viz., Is cyanogen burning in the Bessemer flame? Again, we have another set of workshop facts and laboratory experiments which go to show that for the production of steel, hydrogen in the form of hydro-carbon is necessary. It is well known that coal gas, paraffin, and other hydro-carbons, are more efficient cementing agents than pure carbon. Dr. Percy found that the charcoal of sugar, which retained some hydrogen or hydro-carbon, readily converted iron into steel, but that the same charcoal failed to produce steel under similar circumstances, after it had been deprived of its hydro-carbon. It is well known that wood charcoal which has been several times heated in the cementing furnace, loses some of its power of cementation, and this has been attributed to the driving off of the hydro-carbon contained in the fresh charcoal.

Again, it is found that when, by means of an acid, we dissolve the iron of steel or white iron away from its carbon, the residue is not simple solid carbon, but an unmistakeable liquid hydrocarbon, an oil which, like other hydrocarbons, burns with a smoky flame. In this case it is possible that the hydrogen may be supplied to the carbon by the water or the acid. If so it presents an interesting case of the formation of what we usually regard as organic matter from inorganic materials.

If, on the other hand, the hydrocarbon exists ready formed in the steel and the white iron, the conversion of grey iron into white iron, *i.e.* of graphite into this hydrocarbon, is a still more remarkable case of the same kind.

It is true that the hydrogen may be detected by a direct combustion analysis, but this does not reveal the mode of its existence. The information thus afforded is analogous to what we obtain by similar means respecting nitrogen.

The last change that occurs in the flame, that which announces to the foreman the time for stopping the blow, requires but little explanation; but it is, nevertheless, instructive if thoughtfully examined. The contraction of the flame and loss of brilliancy is evidently due to the exhaustion of the carbon. The change which occurs is very similar to that which is observed when air is admitted to a jet from which coal gas is burning.

If to such a jet, supplied with a constant quantity of coal gas, atmospheric air be admitted, so that it shall mix with the gas before burning, the white or luminous portion of the flame will contract in proportion to the quantity of air supplied, and if a gradually increasing quantity of air be admitted, this contraction will progress until the white flame is totally extinguished. Mr. Jonathan Wilkinson, of Grimesthorpe, who has been recently investigating this subject with a view to practical photometric applications, finds that the quantity of air required thus to extinguish the white flame is proportionate to the quantity of carbon combined with the hydrogen, or to the illuminating power of the gas,—that for every standard "candle" of illuminating power about 0·2 of air is required. Thus fifteen-candle gas will require three times its own volume of air at the same temperature and pressure for the extinction of the white flame, seventeen-candle gas 3·4 of air, and so on.

In the case of the Bessemer flame, we have a constant supply of air to a diminishing supply of carbon, and therefore we may expect that there should occur in the white portion of the flame due to hydro-carbon a change corresponding to that which would occur in Mr. Wilkinson's photometric flame, if, instead of a constant supply of coal gas mixed with an increasing supply of air, he maintained the air in constant flow and gradually closed the gas-cock. In this case there would not only occur a gradual diminution of the brilliancy but also of the dimensions of the flame.

Such is the change which takes place in the Bessemer flame towards the end of the blow, and it so far confirms the hypothesis that a *considerable portion* of the white flame is due to hydro-carbon. If it were due to the combustion of iron the white flame should increase towards the end of the blow, for it is then that the iron, when no longer protected by the more combustible carbon, begins to burn in a serious degree, just as I have shown that the full combustion of the carbon takes place after the bulk of the silicon has been oxidised.

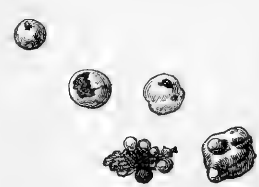

FIG. 3.

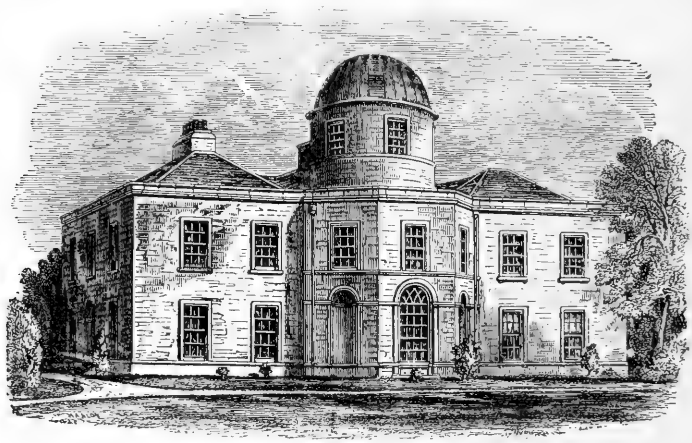
W. MATTIEU WILLIAMS

THE OBSERVATORY OF TRINITY COLLEGE, DUBLIN

IN 1774, Dr. F. Andrews, Provost of Trinity College, Dublin, died, having bequeathed to the College the sum of 3,000*l*. to build and furnish an Observatory, and a further annual sum of 250*l*. as payment of a Professor of Astronomy. Unfortunately, litigation arose, and it was not until about 1781 that it was settled. In 1783 Dr. H. Ussher was appointed Professor; in 1788 the present site of the Observatory was purchased and the buildings erected. Ramsden was commissioned to build the transit instrument, but innumerable delays occurred, and it was not set up until 1808, eighteen years after Professor Ussher's death, and during the professorship of Dr. Brinkley. In 1791 a License of Mortmain, together with a statute for regulating the duties of the Professor, were obtained, and the College expended out of their private funds several thousand pounds, so as to carry out the intentions of their late Provost. The competition for the professorship is open to all the astronomers of Europe. Since its foundation four have been appointed: Dr. Ussher, in 1783; Dr. J. Brinkley, of Cambridge, in 1790; Sir William Hamilton, in 1827; and Dr. Francis Brünnow, in 1865. The Professor of Astronomy is also Astronomer Royal for Ireland. Since 1831 the stipend granted to the Professor is 700*l*. per annum, which includes the pay of an assistant and gardener.

The Observatory is situated about five miles from the College, at Dunsink, to the north-west of Dublin, beyond the Phœnix Park. It lies amid extensive fields and pasture lands on the summit of a hill nearly three hundred feet, close to the sea level. The accompanying woodcut represents the principal front of the Observatory. By the Statute of 1791 it is enacted, among other things, that a fair copy of the observations made every year shall be presented to the College, and also that the observations shall be printed every year at the expense of the College, the Professor to supervise the press, and copies to be sent as presents to the principal observatories, academies, libraries, and eminently-learned persons both at home and abroad; the remaining copies to be sold, and the profit given to the Professor for his care and trouble in supervising the printing of the observations.

We welcome with great pleasure the first part of a series of "Astronomical Observations and Researches made at Dunsink" by the present Astronomer Royal for Ireland, which has been printed and circulated within the last few weeks by the College. It consists of a quarto part of eighty-eight pages, and it is accompanied by three plates. It embraces the results of observations made with the "south" refractor, from June 1868 to October 1869, and contains—1. Description of the "South" Refractor. 2. New determination of the Parallax of α Lyræ. 3. Determination of the Parallax of 61 σ Draconis. 4. Micrometrical measurements of double stars. 5. Observations of α Lyræ and companion; and 6, Observations on 61 σ Draconis. The plates represent the new dome erected for the "South" Refractor, a sketch of the wheels on which the dome revolves, and the interior of the dome and sketch of the "South" Refractor.



THE OBSERVATORY OF TRINITY COLLEGE, DUBLIN

The object glass of this Refractor was given in 1863 to Trinity College, by Sir James South. It was given with a valuable collection of astronomical instruments on the accession of the Right Hon. the Earl of Rosse as Chancellor of the University. This glass is 11¾ inches diameter, and was purchased by Sir James South forty years ago from Cauchoix in Paris. The good qualities of the glass had already been fully appreciated by Arago, who recommended the French Government to purchase it for the Paris Observatory. Shortly after the appointment of Professor Brünnow, the Board made arrangements for procuring a mounting, and for erecting a suitable dome. The wall of the dome is of stone, neatly panelled on the inside with wood; the dome is of timber covered with copper; the diameter of the building is 27 feet. The machinery for moving the dome is very ingenious, and was designed and executed by Mr. Grubb. The dome can be started by applying a force of six pounds, while five pounds suffice to keep it in motion; its opening is 2½ feet wide, and extends from the horizon to a little beyond the zenith. The support, or the mounting, is solid pier-built on the limestone rock. The equatorial mounting was made by Mr. Grubb. The motion of the clock is very steady, keeping a star steadily on the wire. The Filar micrometer was made by Pistor and Martins, of Berlin.

The present series of observations show what work can be done with this excellent instrument in the hands of the present Professor of Astronomy, while they also reflect credit on the Board of Trinity College for their large but wise expenditure.

W.

THE SUPPOSED FUNGOID ORIGIN OF CHOLERA *

THIS report contains a first instalment of the scientific portion of the Cholera inquiry now proceeding in India, the instructions for which were drawn up by the Army Sanitary Commission. It is limited to facts bearing on the Cholera theories of Hallier and Pettenkoffer. In the pursuit of these facts Dr. Lewis has been able to clear the ground for future progress, while at the same time he has added considerably to our knowledge on some obscure points of microscopical science. The report is fully illustrated with engravings of microscopic slides, executed with remarkable beauty and correctness in the office of the Surveyor General of India. Indeed whether we look at the engravings or the typography, we cannot help feeling that our own artists have something to learn from their brethren in India in these matters.

The subjects of examination are divided by Dr. Lewis into three classes, *Cysts*, *Spores*, and *Micrococcus*, the three elements of Hallier's theory; and the examinations have been conducted partly by direct observations of immediate choleraic discharges, in comparison with observations on other media, partly by the use of reagents, time and temperature, and partly by cultivation experiments. In this way, although the microscopic pathology of cholera has still to be inquired into, Dr. Lewis has been enabled to give a satisfactory account of a number of objects which have formed the bases of preceding theories. He has shown what these objects *are not*, and he has shown what many of them *are;* and this he has done with so much scientific caution that we cannot help feeling that this most important inquiry has fallen into proper hands.

In the year 1866 Hallier discovered in cholera discharges, yellowish-coloured cysts of spherical or oval form, enclosing yellowish shining spores varying in size, also groups of swollen spores surrounded by minute molecular matter (so-called *micrococcus*) proceeding apparently from the rupture or breaking up of spores.

These minute molecules were seen to adhere to various objects in the fluid, on which they appeared to feed; they exhibited signs of germination, groupings, filamentary arrangements, and, finally, branching filaments with *macroconidia* and *cysts*, the relations of which to each other were considered as established by cultivation experiments. The resulting fungus, a *polycystus*, was considered by Hallier to resemble the rye fungus in Europe, and probably to be present in diseased rice in India; and he held that this fungus introduced into the intestinal canal and there passing through the various stages of its existence, caused the phenomena of cholera by its action on the intestinal epithelium.

This brief sketch is sufficient to show how much solid fact was necessary to fill up the slight frame-work of Hallier's hypothesis. Here Dr. Lewis's work begins, and every step in it is illustrated by engraved slides.

We have first an examination into the nature of the so-called "cholera cells" discovered by Drs. Swayne, Brittan, and Budd, in 1849. These objects appear to have been of various kinds; some certainly not of fungoid origin. Selecting the most marked of the objects of which engravings are given, Dr. Lewis shows that objects, as nearly as possible similar to those figured by the Bristol observers, are found in discharges in India, and that they are ova of *acari* and of intestinal worms (*trichocephalus*).

As regards Hallier's *cysts* Dr. Lewis states that he has never met with any in fresh cholera discharges, but that he had repeatedly developed them. The other cyst-like bodies proved to be either fragments of tissues or ova, none being peculiar to cholera. Cultivation experiments with cholera discharge containing cyst-like bodies yielded branching fungi with *macroconidia*, which gave place to *aspergillus;* in other cultivations, however, the only products were *penicillium* and *aspergillus*. Dr. Lewis admits that cysts distinctly resembling those of Hallier may be developed by cultivation from cholera discharges, but that he had found them only three times in more than a hundred cultivations.

Their development is therefore not a constant phenomenon, and Dr. Lewis further shows that cysts of the same character can be developed in discharges not choleraic. Bodies resembling "*spores*" are very common in cholera discharges, and Dr. Lewis bestows much pains in demonstrating their true nature. He illustrates every step of the inquiry by slides, and classifies the bodies under the four following heads:—(1) Globules, of a fatty nature; (2) altered blood cells; (3) corpuscles, embedded in a tenacious substance; (4) globular condition of certain infusoria. The corpuscles in Class 3 are amœboid in character, and are probably due to effused blood plasma. There is no evidence of the presence of spores of fungi.

The last subject inquired into was the so-called micrococcus, the supposed "germ" of cholera, which in Hallier's view might pass into the human body in water or air, and then give rise to cholera by developing itself at the expense of nitrogenous material, especially intestinal epithelium.

Dr. Lewis shows that minutely divided matter is not more prevalent in choleraic than in other discharges, indeed less so, but that attempts to produce "*micrococcus*" by cultivation had entirely failed, possibly on account of the many sources of fallacy in such experiments.

He gives the results of a number of observations made with infusions and decoctions of animal matter, including cultivations with cholera discharge, and shows that in spite of every care in the manipulations, very different forms of life will make their appearance in substances derived from the same source, and under apparently identical conditions. His general conclusions on this first stage of the inquiry are:—

1. That no cysts exist in choleraic discharges which are not found under other conditions. 2. That cysts or "sporangia" of fungi are very rarely found under any circumstances in alvine discharges. 3. That no special fungus has been developed in cholera discharges, the fungus described by Hallier being certainly not confined to such. 4. That there are no animalcular developments, either as to nature or proportionate amount peculiar to cholera, and that the same organisms may be developed in nitrogenous material even outside the body. Lastly, that the supposed *debris* of intestinal epithelium is not of this origin, but appears to result from effused blood plasma.

Unless these conclusions are materially modified on subsequent inquiry, they must be considered as disposing of Hallier's theory of cholera. Should, however, Dr. Lewis's further investigations prove that Hallier's fungus is present in choleraic discharges and in diseased rice as a *constant*, we should still require scientific proof that cholera was caused by the action of this fungus and by nothing else.

Pettenkoffer's theory of cholera connects the prevalence of the disease with certain conditions of damp subsoil and subsoil water besides the presence of a "germ," favourable meteorological conditions and personal predisposition. Little has been done as yet in this portion of the cholera inquiry. What has been done is very interesting, although it does not support the theory. Observations regarding it have been made at Allahabad, Cawnpore, Lucknow, Fyzabad, Agra, Morar, Meerut, and Peshawur. The subsoil water experiments do not appear to sustain Pettenkoffer's views, but the examination of soils has yielded several important scientific facts of general interest. The amount of air in specimens of soil taken at different stations varies from 33 to 66 per cent.

* A Report on the Microscopic Objects found in Cholera Evacuations, &c. By T. R. Lewis, M.B., Assistant Surgeon H.M. British Forces.

by measure. The amount of organic matter in soils, when compared with the amount, weight for weight in the water at the same stations is from 10 to 20 times greater; one instance is given in which it was 40 times greater. But the most interesting scientific facts are those connected with the development of lower forms of life in infusions of soils in water. Besides a few *algæ*, the prevailing forms are—*Monas lens*, *Paramecium*, *Monera* assuming the most fantastic outlines, *Vibriones*, *Amœba*, *Englenæ*, &c.

We look forward with great interest to further instalments of this important inquiry, which we trust may add largely to our knowledge, and by this means enable human life to be saved.

FOSSIL CETACEA

DURING the recent extensions of the fortifications of Antwerp, which have occupied some years, very fine opportunities have been offered, as is well known to geologists, for studying the Crag formations (Diestien and Scaldisien systems) of Antwerp, of which we have remnants on our own east coast. It is not, however, so well known that the Belgian Government during the excavations used every care to preserve the remains of Cetacea and other marine mammalia thus disinterred. The workmen were instructed to give up all such remains for the Government, and were not allowed to sell them. Parts of the Black and Grey Crags proved to be a complete charnel house—so abundant were the remains—and these have been quietly brought together and placed under lock and key for the last eight years. The richness of the fauna disinterred may be judged from the fact that it is stated that eight new genera of Ziphioid Cetaceans are indicated besides sixteen new species belonging to known genera. Many of the forms are represented by far more complete portions of the skull than have hitherto been known from these beds, also portions of the trunk, limbs, and lower jaw in connection with these. Portions of the skull of the fossil Walrus, tusks of which occur in the Suffolk bone-bed and have been described as Trichecodon, have been obtained, as well as remains of seals. All these specimens are under study by the Vicomte du Bus, and are not open to the inspection of even professional palæontologists. They are being carefully and freely engraved, and will soon, it may be hoped, be made known to the world.

PARASITES

PROF. VON BENEDEN, as we have before noticed, has distinguished true parasites, which live *on* their host, from commensals, those which live merely *with* their host, the thieving impostor from the respectable lodger. In an admirable work on the "Fishes of the coasts of Belgium, their Commensals and Parasites," published by the Academy of Sciences of Brussels, he now further classifies parasitic organisms. The commensals are either 1, *Oikosites*, fixed; or 2, *Coinosites*, free. The Oikosites fish for their own living, and merely ask a free passage from their hosts. They are either fixed in perpetuity, as *Coronula*, *Cochliolepis*, *Modiolaria*, *Mnestra*, and *Loxosoma*, temporarily as the *Remora*, *Anilocra*, *Praniza*, or only in the young state, *e.g.*, *Caligus* and *Anodon*. The Coinosites, on the other hand, never give up their liberty; they occasionally leave their host, and between Coinosite and host there is often an exchange of good offices, one furnishing a solid house or a strong claw, the other a sharp eye, and they may share their prey in common. The digestive canal is occupied by the following Coinosites:—*Fierasper*, *Stegophyle*, *Stylifer*, *Phronimus*, *Hyperia*, the mantle by *Pinnotherus* and *Pagurus*, the exterior by *Myzostoma*, *Cyamus*, *Pycnogonon Caprella*, and *Chætogaster*.

The true parasites cannot live without assistance, they are divisible into several categories. Some, such as the leech, fleas, and some dipterous insects, suck the blood of their victim, and then quit him to take their after-dinner nap in the open air; others, such as the ichneumon flies, do not quit their host till they have become adult, and have in the process exhausted the last drop of blood of their unfortunate prey. The greater number lead a free life when young, and merely attach themselves to a host at the time of reproduction, such are the Bopyrian and Lernæan Crustacea. There is a further very interesting group, who enter a host while yet young, simply in order that they may get carried by its means into a second host, where they will ripen their eggs. Often whilst waiting in their first host (sometimes vainly waiting no doubt) for him to be devoured by their second and ultimate victim they reproduce *agamically*. Such parasites are the Flukes and many Tapeworms. These divisions are thus tabularly set forth:—

Parasites free			
during all their life.	during a part of their life they pass through		
Leeches. Fleas and Flies. *Caliga.*	a single host.		several hosts whilst immature.
	whilst immature. Ichneumons. *Mermis.*	when mature. Bopyrians. Lernæans.	Distomata. Cestoids.

The parasites of the first category which are free during all their life, Professor Van Beneden calls Phagosites, and compares them to the *habitués* of a hotel who avail themselves of the *table d'hôte*, but do not have a bedroom in the building. The other parasites which have both board and lodging are divisible into three principal categories. 1st. Xenosites—who are pilgrims in transit—voyaging with a distinct but distant object in view. They are always agamic, lodge in such closed organs as the brain, muscles, and serous membranes, and wait patiently till they get into the stomach of the animal where they are destined to breed. The stomachs and appendages of fishes swarm with parasites, and those which have the largest *clientèle* are by no means the least healthy or thinnest. Often one fish, having swallowed another, is swallowed by a third, and thus Xenosites find themselves set free in the wrong fish's stomach, for the stomach acts like a filter, straining out and retaining the parasites, while the flesh is digested. Such erring Xenosites merely wait, and may often pass through several "hotels" before they reach their destination. 2nd. Nostosites—those who have reached their destination, and now can abandon themselves to generation. Whilst the Xenosite was obliged to put up often with an uncomfortable cramped lodging, biding his time, the Nostosite occupies the most eligible organs for parasitism—in fact, the most vast and commodious chambers of the hotel. The 3rd division are the Pilgrims, who have lost their way hopelessly, and are in worse plight than even in Giant Despair's castle. Such are the agamic worms which are found often in the Plagiostomous fishes, and who ought to have got into some Teleostean fish, there to fructify—a happy fate for ever lost to them when by unlucky chance the host in whom they trusted was swallowed by a remorseless shark. They never quit this retreat

Professor Van Beneden gives directions for searching an animal for its parasites, and justly claims a high interest for the study of the fauna of individual species, and urges such neat and sharply-limited zoological inquiries on those who do not feel prepared to study the fauna of a geographical region—to the philosophy of which, indeed, the study of parasite-faunæ may furnish important suggestions. Ninety-three species of fish, with their parasites and commensals, are cited in this work from the author's own observation. Eight plates illustrate it.

E. R. L.

NOTES

In the second report of the Royal Sanitary Commission, just published, the Commissioners appear to be under the impression that no branch of science other than that of medicine is to any great extent involved in sanitary questions, and therefore recommend that the 4,000 medical men appointed under the Poor-law Board should be the inspectors under the proposed new sanitary department; mentioning, however, the probability of a variety of officers being requisite for scientific purposes only. We think that, in order to carry out sanitary reform efficiently, the new department should have the means of consulting the highest authorities in most of the branches of physical science, and here, as in many other cases, we see the necessity for a Board of Science, whose duty it should be to advise the Government on all scientific questions.

We regret to state that the work at the new buildings at Burlington House for the learned societies has come to a standstill, owing, we are informed, to the failure of the contractors.

Our Paris correspondent reports the death, at the age of 80, of M. Becquerel, the celebrated electrician. He died in Normandy during the siege of Paris.

The series of afternoon scientific lectures to be delivered in the Lecture Theatre of the Royal Dublin Society is as follows:—March 25—G. J. Stoney, A.M., on the Sun. April 1—Professor Traquair, M.D., on the Vertebrates of the Coal Period. April 8—Dr. C. Cameron, on the Source of Muscular Force. April 15—Professor J. R. Greene, on the Phenomena of Sleep and Dreams. April 22—Professor W. T. Dyer, on Recent Additions to our Knowledge of Fossil Plants. April 29—Professor T. Andrews, F.R.S., on the Continuity of Liquid and Gaseous States of Matter. May 6—Professor P. Redfern, M.D., Illustrations of the Advance of Physiology. May 13, Dr. J. E. Reynolds, on the Chemistry of Milk, and a new mode of testing its quality.

We are glad to hear that the Hackney Scientific Association is in an active and prosperous condition. In another column we print a very short abstract of a paper read at a recent meeting on the fossil remains of mammalia found in the Lea Valley.

The *Moniteur Scientifique*, edited by Dr. Quesneville, is the only scientific paper which continued to be published in Paris regularly throughout the siege. Since the 1st of October its circulation has been necessarily confined to its subscribers in Paris; but we have now received a parcel of ten of its fortnightly numbers, and heartily commend it to the notice of men of science in England.

The following is the substance of a communication on the periodicity and heliographic distribution of sun-spots, addressed by M. Zöllner to the *Astronomische Nachrichten* or March 2nd:—The sun-spots are slaglike by the radiation of heat on the glowing and liquid surface of the sun; the products of the cooling having again dissolved, in consequence of the disturbance of equilibrium produced by themselves in the atmosphere. When these disturbances are not only local, but generally distributed, the formation of new spots is but little favoured at the times of such general motion of the atmosphere, because then the most essential conditions of the surface are wanting for a severe depression of temperature by radiation, namely, the rest and clearness of the atmosphere. But when the surface has again gradually become quiet after the dissolution of the spots, the process again recommences, and acquires in this manner a *periodic* character, in consequence of the mean relationships of the surface of the sun, which may be considered as attaining an average in long periods. The distribution of the spots in area must, according to this theory, be determined by the zones of greatest atmospheric clearness, which, as has been shown, generally coincide with the zones of the greatest abundance of spots.

The following are our American notes for the week, for which we are again indebted to *Harper's Weekly*:—The eighty-fifth number of the Proceedings of the American Philosophical Society, lately published, and completing the eleventh volume, is, like many of its predecessors, nearly filled with important communications from Professor Cope, whose industry in publishing accounts of new, recent, and extinct zoological forms is untiring. One of the most important of these communications is an article upon certain fresh-water tertiary fishes from Idaho, collected by Mr. Clarence King, and embracing twelve species of six genera. These all belong to the Cyprinidæ, with the exception of one species of the trout family. With these fish were three species of *Astacus*, also described by Professor Cope in another communication.—We have already referred to one of the papers of Professor Cope, in which he describes a new species of mosasauroid, called *Liodon dyspelor*, based upon specimens from New Mexico in the museum of the Smithsonian Institution, and which, according to Professor Cope, probably exceeded one hundred feet in length, and may be considered as the longest reptile of which we have any account.—We have frequently called attention to the interest and value of the dredging operations conducted by Count Pourtales in behalf of the coast survey, in the deep seas adjoining the southern coast of the United States. The results of these labours are being published by the Museum of Comparative Zoology at Cambridge, Massachusetts; and there has just appeared an elaborate memoir upon the crustaceans by Dr. William Stimpson, of Chicago. A large number of new genera and species were detected in the collection, and a portion of these are numerated in the report referred to, which embraces only the Brachyura, the remaining families being reserved for a future memoir.—The Commissioners of Fisheries for the State of New York have lately announced in the public papers their readiness to furnish, free of expense, living black bass, cat-fish, white bass, rock bass, roach, perch, sunfish, and pike-perch, for stocking the waters in any part of the State of New York, provided parties desiring them will send an agent to receive and take charge of them. All of these are now bred at the State establishment at Caledonia, and applications for them are to be made to Seth Green, Rochester.—One result of the completion of the Pacific Railroad has been the introduction into Eastern markets of Western game. We see it stated that two hundred antelope were sent to Boston during a single week, and three hundred saddles of deer, of both the white-tailed and black-tailed species. The antelope brought from fifteen to twenty cents per pound wholesale, and the venison from twenty to twenty-five.

The first annual report of the Association for the Improvement of Geometrical Teaching has just been issued. Gentlemen who may desire to have a copy of the same, or to receive information on matters connected with the Association, will perhaps be glad to know the names of the local London secretaries, who are Mr. C. W. Merrifield, F.R.S., Royal School of Naval Architecture, South Kensington, and Mr. R. Tucker, M.A., University College School, W.C.

The Proceedings of the Royal Asiatic Society of Bengal for January contains a drawing of a remarkable case of polydactylism in a horse from Bagdad. Mr. Wood-Mason, who exhibited the specimen, remarked that the splint-like rudiments of the metacarpals of the fourth toe on each fore foot had given rise to a supernumerary digit provided with the regular number of phalanges, and encased in an asymmetrical hoof, the asymmetry of which was such that the presence of another of the same shape internally to it would have formed a symmetrical pair like the cleft hoof of a ruminant. The metatarsals of the fourth toe on each hind foot were, by the law of correlation, similarly affected; but the supernumerary hoofs of these were stouter and more irregular in shape. The monstrosity appeared to present an interesting reversion in the direction of the extinct and fossil *Hipparion*.

ONE of the "A B C Despatch-boxes," patented by Jenner and Knewstub, has been forwarded to us. We hail it as a most useful invention for all who have papers to keep in order—a condition which largely obtains in the case of scientific men, and we commend it accordingly.

ON the night of the 26th January some severe shocks ot earthquake were felt at Accra on the West Coast of Africa. As three series had been felt in five months there was considerable alarm.

MR. HYDE CLARK will bring before the Anthropological Institute on Monday the result of his researches on the ancient history of civilisation, and the development of comparative mythology in Western Asia and Europe, previous to the Aryan period.

COAL has been found at Sarawak in a district easy of access, and where native labour is easily obtainable.

INDIAN papers, in reporting an earthquake shock in Assam on January 27th, give two native theories of the causes and origin of earthquakes. The one is that when the world becomes sinful, a kind of large serpent, on which the world rests, turns on its side, and so causes them. The other is, that earthquakes are caused by periodical leaps of the mountain gods from one mountain to another.

THE Folkestone Natural History Society has issued its third annual report, from which we gather that its progress is still satisfactory. The number of members now reaches 150, showing an increase of thirty-two during the past year. The attendance both on field days and at the *conversazioni* has been, on the whole, very good. The expenses attendant on the reorganisation of the museum have been somewhat heavy, and an appeal is made for the formation of a museum fund, which it is hoped will meet with a suitable response. The report contains a selection from the papers read during the year, those published being: "On Primroses and their Fertilisation," by the secretary, Mr. Ullyett; "On Arctic Botany," by the president, Dr. Fitzgerald, who accompanied Lord Dufferin on his voyage to the North Pole some few years since; "On the Special Characteristics of Seaside Plants;" "On the Yeast Plant;" and "Local Botany." We are somewhat disappointed that more prominence is not given to local natural history; but, with this exception, the report is very creditable, although a little more attention might have been advantageously bestowed upon the printing of the scientific names. A list of the books given and lent to the library concludes the report.

DR. FAYRER, in India, has been experimenting to correct the popular error that a snake cannot kill a snake. He took a young and very lively cobra fourteen inches long, and which was bitten in the muscular part of the body by a krait forty-eight inches long. The krait had not bitten for some days before. From a detailed report by Dr. Fayrer, it appears that the cobra was bitten at 12.50 P.M., at 1 P.M. it was very sluggish, at 1.3 P.M. so sluggish that it moved with difficulty, could be easily handled, and made no effort at resistance. At 1.20 it was apparently dying and its movements were scarcely perceptible, and at 1.22 it died, thirty-two minutes after the attack. Dr. Fayrer has found that the water-snakes of India are deadly poisonous. In the Bay of Bengal they swarm, and it is noted as ominous that lately it was proposed to erect a sea bathing establishment for Calcutta at Barwar, under the assurance there were no sharks. It is remarked that sharks need not be noticed when a bather may have deadly water-snakes swimming after him.

THE *Correspondenzblatt* of the Naturalists' Society of Riga, 1870, contains an abstract of a paper by Herr Teich, "On the influence of climate on the size, colour, form, and number of species of butterflies:"—An account of a discovery by Prof. Nauch that thin glass tubes when they have a ball blown at their ends give out a distinctly audible and clear note on cooling so long as the relation of the size of the ball to the length of the tube does not pass a certain limit. The sound is ascribed to vibrations set up by the inrush of air consequent upon cooling. Some remarks by the same professor on a lightning tube found at Ilgezeem:—A long paper on cell life by C. A. Hengel:—A communication from Herr Thieme to the effect that he has found that *Dracæna paniculata* kills flies, particularly when the plant stands several feet from the window. The dead flies hang to the under side of the leaf:—A paper by A. Nöschel on the Trevelyan instrument, the sound produced by which he considers due to friction between the two metals—the one contracting, whilst the other expands, the vibratory movement being considered as secondary. The author calls attention to the fact that when the instrument has been in action for some time a bright spot is formed on the metal at the point of contact, which he considers as evidence in favour of his theory. Baron Horyingen Huene gives an account of a plan of sugaring for insects with apples cut in three soaked in solution of honey for a day, then strung on string, and suspended between adjacent trees, which he has found very successful. The journal contains many other communications, but without much original matter in them.

A REPORT comes from Bangalore in the Madras presidency, that coal and paying gold have been found.

AN Australian is said to have raised a sum of money by a false representation of the existence of coal at Midnapore in Bengal.

A SLIGHT shock of earthquake was felt at Guyaquil in Ecuador on the 9th January. The movement was from the interior towards the coast.

AN eruption of the Colorucco volcano in Mexico in January has done much damage to plantations and villages. An eruption of Mount Orizaba is expected.

ON the night of the 31st January an earthquake was felt at Bombay, which extended over a large tract of country. It is stated that on New Year's Day Northern Guzerat had a like visitation.

BESIDES the objects brought from the Guano Islands of Guanape, on the coast of Peru, by Mr. Josiah Harris, and exhibited at the Ethnological Society last year, we have now the report of a large find. The most interesting objects are rude representations of the human figure, cut in very hard wood. On the north island, beneath forty feet of guano, a cavity was come upon, which, on the removal of the guano, was found to be a cave, leading downwards further forty feet. This was a kind of Pompeii, but blocked with bird dung instead of volcanic ashes. It had been evidently frequented by man, and contained many handwrought works, and also well-preserved seafowl and other birds, lizards' eggs, but all petrified, as it were, in the guano. In many cases the colour of the eggs is preserved. The cracks and fissures in the walls of the cave were found filled with solidified ammoniacal salt. Two pieces of earthenware vases were found, bearing figures, also two gold earrings, and a bundle of medicinal herbs tied up in woven cloth. Local antiquaries consider the objects as far older than the time of the Spanish conquest. The point of interest is the accumulation of guano above the surface.

WE learn from the *British Medical Journal* that Dr. Crace Calvert, of Manchester, having been requested to carbolise a quantity of charpie for the use of the ambulances at the seat of war, found that charpie was unsuitable for the purpose; and after trying several textures, finally hit upon oakum as the most excellent. The oakum is first soaked in Burgundy pitch, and then rendered antiseptic by the addition of carbolic acid. This application has been a good deal used at the Manchester Infirmary, and with good results.

A NEW undertaking of interest to the philosopher is the Arequipa Railway in Peru just opened for traffic. It is a great engineering work, carried out with English capital by American enterprise, and it penetrates the western chain of the Cordillera of the Andes to reach the table lands of the interior, Arequipa, the terminus, being 7,800 feet above the level of the sea. Now at this elevation the rarefaction of the air is such that the ordinary workmen could not be employed, the suffering being in some cases intense. The works were, however, pushed on with vigour, and Mr. Meiggs imported above 16,000 labourers for his works, and for this purpose chiefly Aymara Indians from Bolivia. Mr. David Forbes, F.R.S., has, in his memoirs on the Aymaras in the Journal of the Ethnological Society, described the abnormal structure of the chests of these people, and it is astonishing to see them employed in a task which most effectually insures their subjugation. To foreign troops it was always difficult to scale these regions, but now the railway does the work, though to soldiers and passengers the journey is not always without discomfort.

THE Bunya-Bunya (*Araucaria Bidwilli*), a native of the northern district of New South Wales, is of considerable interest, as being the only hereditary personal property possessed by the natives, who greedily devour the fruit, either raw, or roasted and made into cakes. This fruit is only plentiful every third year; and at the proper season the aborigines assemble in considerable numbers for the purpose of obtaining it. Each tribe has its own set of trees, and each family its particular individuals among them; and these are handed down from generation to generation. The right of ownership is almost universally respected; but occasional depredations occur, when a fight ensues, the sympathies of the bystanders going with the lawful proprietor.

WE learn from the *Grocer* that experiments recently carried on in India have proved that coffee pulp will yield, upon distillation, 9 per cent. of its own weight of spirit, equal in strength to Scotch whisky. Nothing is said as to the flavour of this spirit in its raw state, but it appears to realise on the spot a price nearly equivalent to 4*s*. 6*d*. per gallon.

AT the end of January, no date named, a shock of earthquake was felt in the Sanjak of Kartal, in Northern Asia Minor, which lasted several seconds and did slight damage.

A LARGE and valuable deposit of limestone has been discovered by Mr. Read in the Sonthal Pergunnas, in Bengal, in the Banslo River. There is good communication with Calcutta by water or railway.

SOME fair pearls have been brought down to Durban, in Natal, from the River Vaal. They were found in mussels.

NATURAL history and dancing and the Police. Such is our announcement from Madras. In consequence of a fatal case the Commissioner of Police has ordered that the dancing girls shall not dance in the Hindu temples with cobra snakes thrown round their necks. This will cause great disappointment to the pious votary and the interested amateur. It will tend, however, to lessen the reverence for the cobra, and may bring his tribe into greater danger of repression.

IMAGINATION IN SCIENCE

PROFESSOR Tyndall will eventually have much to answer for. He has lent his authority to the admission of imagination in the pursuit of science, and there is every prospect that people whose imaginative faculty is stronger than their habit of observation will give us all plenty to do. We shall not only have to question nature, but we shall have to eliminate imagination, and thus have two battles to fight for truth. Our medical friends have not always walked in the ways of rigid observation and induction, but if any one desires to see how easy it is for the imaginative faculty alone to tell us all we require to know, we commend to his perusal the *Mobile Daily Register*, of Dec. 18th, 1870, in which there is a communication from Dr. Cochrane on the subject of yellow fever, well written, and interesting, and giving what may be called an account of yellow fever from the imaginative side. The author justifies his position by the example of European names, tells us candidly that he states only "what he believes but does not know," and then takes his flight into the unknown. He imagines "the yellow fever poison to be composed of living germs in innumerable number, living organisms of inconceivable minuteness, which eat, and drink, and multiply their generations under the sun, just as other living creatures do with which we happen to be familiar." He connects his speculations in these matters with similar speculations about "contagia" and disease "germs" which are well known on this side of the Atlantic, and without paying any attention to facts regarding yellow fever and other diseases which are left untouched by any extant doctrine, he tells us truly that "the visions of modern science are more wonderful than the visions of Eastern fable." This may be true, and the visions themselves may be true; but, for people who feel that they must walk over the earth in search of truth, nutriment of this kind is by no means sufficient for mental sustenance.

We have no desire to undervalue the importance of the imaginative faculty in scientific pursuits; but papers such as the one before us raise some very important primary questions. Are we to live, scientifically, in the same way as alchemists and astrologers did in the Middle Ages? and are we to ignore all that Bacon and Newton have done for us? If it be true that there is no royal road to knowledge on the firm earth, it is certain there is no such road through the air. Let us use the imaginative faculty by all means; but, in doing so, let us take our stand on the firm ground of the known before we venture ourselves into the unknown.

THE ROYAL SOCIETY'S SOIRÉE

WE are indebted for the following account of the most interesting objects exhibited at the Royal Society's *soirée* on Saturday evening last to the *Standard*, from which paper it is abridged.

In the foremost ranks of notable attractions were the heliotype process of printing photographic plates for plates for book illustration, by Messrs. Edwards and Kidd; the solar eclipse photographs, and the twelve-inch equatorial telescope, with its photographic feed apparatus (Mr. Browning's), by which they were obtained by Lord Lindsay; the musical vibration figures shown in Mr. Spottiswoode's new apparatus; the electrical experiments of Mr. Varley; Commander Harvey's sea torpedo (made by Vavasseur); Dr. Norris's soap-bubble experiments; Mr. Haviland's fine maps of the geographical distribution of cancer and heart disease (very recently published by Mr. Keith Johnston); the gold-hardening process, by Mr. Roberts of the Mint; and Mr. Francis Galton's pantagraph and resultant plates for the publications of the Meteorological Office.

The soap-bubble experiments, performed with great adeptness by Dr. Norris, were intended to illustrate the physical principles concerned in the formation of rouleaux in the blood and in the passage of the corpuscles *de toute pièce* through the walls of the minute blood-vessels, without rupture of the latter, as observed by Waller in 1846 and Cohnheim in 1867. A film of soap solution was taken by a metal ring of a foot or more in diameter, and upon it a soap-bubble blown from a pipe was thrown; the bubble was caught by the film, and held suspended midway or along the equator of the thin hollow sphere. The bubbles were then forced through and drawn through without rupture of the films. An orange was dropped, and glass rods and other solid objects, with wetted surfaces, were passed in like manner without rupture of the films.

The three experiments by Mr. Cromwell F. Varley were exhibited for the first time in public. Two of them were in illustration of some investigations into the nature of electric discharges through gaseous media, described in a paper read before the society in January. In a Geissler's tube, containing highly rarefied hydrogen, a small filament of talc was hung by a single horizontal fibre of silk. Two aluminium rings, separated an inch and a quarter, formed the electrodes inside the vacuum. This tube was placed longitudinally with and over the horizontal poles of a large very powerful iron horse-shoe electromagnet, made of a bar four inches in diameter and four feet in length, and wrapped with nearly 2 cwt. of thick copper wire. A small induction coil sent electric discharges from one ring to the other, producing a brilliant blue light around the negative pole, the positive pole being dark. The moment the magnet was charged, by means of thirty cells of Grove's nitric acid battery, each cell containing twenty square inches of platinum foil, the electric luminosity in the tube, which beforehand was diffused, gathered up into an arch extending one and a half inches beyond each ring, forming altogether a well-defined arch about four inches in length. This luminous arch follows exactly the course of those magnetic rays which traverse through the negative pole. By shifting the tube the piece of talc can be brought at pleasure in or out of this luminous arch. Neither the electric action nor the magnet *per se* produce any motion upon the talc; but when the tube is so placed that the luminous arch strikes against the talc the talc is repelled as much as 30° from the perpendicular. The electric current is passing simply from one ring to the other inside the tube, but the luminous arch in question where it strikes the talc is on the other side of the ring and where no electricity is flowing.

Mr. Spottiswoode's musical vibration experiment consisted of the visible representation of the forms actually assumed by a musical string when producing a note or its harmonies. To show this it is required that the string should be kept in a perfectly uniform state of vibration. This was very ingeniously accomplished by means of tuning forks kept in vibration by electro-magnets, these forming their own breaks in cups of mercury.

The singular action of nuclei in promoting crystallisation has long been known, but recent experiments by Mr. Chandler Roberts, chemist of the Mint, have imparted additional interest to the subject. Minute traces of lead, antimony, bismuth, or arsenic, render the alloy of gold and copper known as "standard gold" crystalline, intensely brittle, and totally unfit for the purpose of coining. This remarkable effect is produced even when the amount of obnoxious metal does not exceed the $\frac{1}{2000}$ part of the mass of standard gold. Mr. Roberts exhibited beautiful specimens of crystalline standard gold and illustrations of the process of toughening brittle gold by means of chlorine recently introduced in the Mint, the adoption of which has afforded a satisfactory solution to a question of considerable importance connected with the manufacture of coins.

SCIENTIFIC SERIALS

THE *Mittheilungen der naturforschenden Gesellschaft in Bern* for 1869, published last year, contain many important papers.—M. E. Schär publishes a valuable contribution to the knowledge of some cyanogen compounds, and a memoir of considerable length on peroxide of hydrogen, and its relations to ferments.—M. A. Gruner communicates a short but interesting paper on the luminosity of the so-called "touchwood," in which he details several experiments, and comes to the conclusion that ozone is to be regarded as the principal cause of the phenomenon.—In geology we find some valuable memoirs by M. C. von Fischer-Ooster, especially a paper on the Rhætic stage in the neighbourhood of Thun, which includes an account of the beds, and a list of the fossils occurring in them, with descriptions of some new species, and many figures. The same author also contributes several smaller papers on the occurrence of a Liassic zone between the chain of the Moleson and the Miremont in the Canton of Freiberg, on the narrow Flysch zone from the Hongrin towards Jaun, on the geological age of the so-called Taviglianaz Sandstone, and on the stratigraphical conditions near the Küblisbad.—M. J. Bachmann publishes some remarks in opposition to M. Renevier's geological observations on the Alps of Central Switzerland compared with the Vaudoise Alps, and M. A. Rytz a notice on the erratic formations in the Kanderthal.—M. Theophil Studer notices the occurrence of Foraminifera in the Alpine chalks, detected by the examination of thin slices, and also describes a new Swiss form of the genus *Tropidonotus*, for which, however, he does not venture to propose a specific name.—Dr. R. Henzi reports upon the attempts made by him to cultivate *Saturnia Mylitta* and *S. yama maya*, and M. G. Hasler describes and figures an apparatus for giving telegraphic intimation of the height of water in reservoirs, &c.—The Proceedings of the society also contain short notices upon various subjects.

THE *Atti della R. Accademia delle Scienze di Torino* for the first six months of the year 1870 (vol. v. parts 3—7) contains numerous papers on various branches of science, but principally on subjects connected with physics. Of zoological memoirs we have a notice of some new and little-known species of birds collected on the voyage of the *Magenta* by MM. Giglioli and Salvadori, the new species being *Acridotheres leucocephalus* and *Leptoptila chloranchenia*; a paper by Dr. Giglioli on the phosphorescence of the sea, with notices of the various animals observed by him to be luminous, and descriptions of two new species of the genus *Noctiluca* (*N. omogenea* and *N. pacifica*); descriptions of new species of birds by M. Salvadori, namely, *Saxicola allo-marginata* from the Sahara, *S. Brehmii* from Nubia and Abyssinia, *Brachypus urostictus* from the Philippines, and the type of a new genus allied to *Malacopteron*, *Homochlamys luscinia* (Finsch MS.) from the Philippines or China; and a critical revision of Antinori's descriptive catalogues of birds collected by him in North Central Africa.—M. Cavalli, in a memoir on a gunpowder uninjurious to cannon, maintains the superiority of large grains, especially if made spherical and more regular and hardened at the surface.—A new form of mercurial barometer is described by M. Faà di Bruno, and the barometric formula of Count Paolo de Saint-Robert is discussed by Prof. Dorna, who also presents what he calls a loghypsometrical table for use in applying the barometric formula worked out by him in the determination of altitudes.—Prof. Govi describes a new method of obtaining sensitive flames, consisting in the application of a wire net with meshes about one millim. square to an ordinary gas jet, and lighting the gas after its passage through the meshes. The same author also publishes a note on the influence of sonorous vibrations upon cold and ignited gas jets.—Prof. Boccardo notices the fall of an earthy shower at Genoa on the 14th February, 1870. He gives an analysis of the material, which consisted chiefly of sand with oxide of iron and carbonate of lime, and contained 6·611 per cent. of nitrogenous organic matter. Under the microscope, it was found to contain frustules of Diatomaceæ and fragments of other simple Algæ. No windstorm had occurred immediately before the fall of the shower, which the author considers to have probably come from Egypt.—Prof. Dorna has a note on the scientific importance of Soperga and the Sacra di San Michele to the Observatory of Turin, and upon their respective differences of level.—M. Richelmy communicates some notes on the construction and operation of toothed wheels.—In a paper on nitroglycerine, nitromannite, and pyroxyline, Prof. Sombrero vindicates his title to be regarded as the discoverer of the first of these compounds, and notices the properties and mode of preparation of the other two. M. L. F. Menabrea furnishes some explanations of his views on the principles of elasticity, which are disputed by MM. A. Parodi and G. Barsotti. M. Codazza describes an apparatus devised by him to act as an electrical indicator to give notice of the attainment of the maximum or minimum limits of temperature between which it is required to keep any substance. Prof. Denza describes an aurora borealis observed in Piedmont on the 5th April 1870.—Prof. Govi indicates that Thenevot was the inventor of the spirit-level with a bubble of air. The same author communicates a paper by Prof. Chiò on a barometric formula.—M. Gastaldi notices a collection of stone weapons and instruments from the neighbourhood of the Baltic, and also some ancient weapons and instruments of stone, bronze, or brass, from Egypt. Several of these are figured; one of them, a long, chisel-shaped, bronze instrument, is attached obliquely to a mallet-shaped handle, in such a manner as to serve as a small axe.—Prof. Luvini publishes a long paper on the adhesion between solids and liquids.—M. Genocchi notices some papers ascribed to A. Cauchy.—Prof. Dorna describes the instruments and methods employed at the Observatory of Turin for the measurement of time.—M. A.

Gras communicates a paper on some botanical synonyms. The plants referred to in the last-mentioned paper are *Lindernia palustris* Crantz, anterior to *L. pyxidaria* Linn., and identical with *Anagalloides procumbens* Krock.; *Scirpus quinqueflorus* Crantz; *Stellaria graminea* Linn.; *Galeopsis segetum* Neck.; *Euphorbia sequieriana* Neck.; and *Statice cordata* Linn., said to be distinct from the species so named by Gusson, which is here noticed as *Statice Gussonii.*

THE Proceedings of the Bohemian Society of Sciences contain several papers by M. Emil Weyr on subjects belonging to the higher mathematics, the titles of which it would be useless to give here. One of his papers, however, is on the curves of maximum and minimum electro-magnetic action.—Dr. A. Grünwald also communicates a paper on some differential equations with variable coefficients, and Prof. Blagek a short notice on the triaxial ellipsoid. The titles of several natural history papers are given; one by Dr. Schöbl on the termination of the sensitive nerves in newly-discovered terminal corpuscles in the wing membrane of the chiroptera, and on the minute structure of the membrane is printed in full. This paper has appeared with illustrations in Siebold and Kölliker's "Zeitschrift für wissenschaftiche Zoologie."—A short notice is given of a lecture by M. Wocel on the significance of stone and bronze antiquities in the primitive history of the Sclavonic tribes, founded on the study of a large collection of casts of such objects from the Ural, Altai, Caucasus, &c.

THE *Verein für Erdkunde* in Dresden published last year its sixth and seventh annual reports, including its proceedings for the sessions 1868–69, and 1869–70. The abstracts of proceedings contain a multitude of short notes upon the results of travels made by members of the Society, and a report upon the doings of the sections of the Society in furtherance of its objects. Besides these, we have in an appendix three memoirs of some importance, namely, contributions to the knowledge of the Hottentots, by M. T. Hahn, relating especially to the language of the "Nama" tribes, but containing besides much interesting matter; a geographical sketch of the Murray and Darling district in Australia, by Dr. H. Beckler; and a curious contribution to the history of geography during the latter half of the Middle Ages, giving an account of the maps and charts of the seafaring peoples of Southern Europe up to the first printing of Ptolemy's Geography, by M. Heinrich Wuttke.

SOCIETIES AND ACADEMIES

Royal Society, March 9.—"Results of Seven Years' Observations of the Dip and Horizontal Force at Stonyhurst College Observatory, from 1863 to March 1870." By the Rev. S. J. Perry.

The object of the present paper is to bring further evidence to bear upon an important question of terrestrial magnetism.

The existence of a sensible semi-annual inequality in the earth's magnetic elements, dependent on the position of the sun in the ecliptic, was deduced by General Sir Edward Sabine from a discussion in 1863 of a continuous series of the monthly magnetic observations taken at Kew. A previous reduction of observations made at Hobarton and at Toronto had first suggested the idea, and a new confirmation of the results has lately been obtained by Dr. Balfour Stewart from subjecting a second series of Kew observations to the same tests as before. The observations, which form the basis of the present discussion, extend over the period from March 1863 to February 1870, during which time the same instruments have been in constant use. These are a Jones unifilar and a dip-circle by Barrow, both tested at Kew, and a Frodsham chronometer. Sir Edward Sabine, who made the Stonyhurst Observatory one of his magnetic stations in the English survey in 1858, greatly encouraged the undertaking of monthly magnetic observations, and the Rev. A. Weld procured in consequence the instruments still in use. Only occasional observations were made with these instruments for some years, and it was only in 1863 that a continuous series of monthly determinations of the magnetic elements was started by the Rev. W. Sidgreaves. He observed regularly until September 1868, when I returned to my former post at the Observatory, and have continued the same work ever since.

A stone pillar was at first erected for the magnetic instruments in the open garden, and this remained in use from 1858 until the beginning of 1868, when a most convenient hut of glass and wood was built for the instruments in a retired corner of the College garden. This alteration was rendered necessary from the placing of iron rails in the vicinity of the old pillar; and although it introduces into the results a correction for change of station, it has the great advantage of securing immunity from disturbance for the future.

Considering the object in view in drawing up this reduced form of the dip and horizontal-force observations, I have judged it advisable to adhere strictly to the tabular forms in which the matter has been presented in previous discussions of a similar nature. Each element is the subject matter of these tables. In the first are the monthly values of the element, the deduced mean value, and its secular variation. Next in order comes the calculation of the semi-annual inequality. The residual errors, and consequent probable weights of the observations and results, compose the third and last table.

The yearly mean values of the horizontal force are found to vary progressively from 3·5926 to 3·6178 in British units, the mean for Oct. 1st, 1866, being 3·6034, with a secular acceleration of 0·0042. Calculating from the monthly tables the mean value of the horizontal force for the six months from April to September, and for the semi-annual period from October to March, we find the former to be 0·0005 in excess over the latter, showing that this component of the intensity is greater during the summer than during the winter months. Treating the dip observations in a precisely similar way, we obtain 69° 45′ 21″ as the mean value of this element for October 1st, 1866, subject to a secular diminution of 1′ 49″·2; the extreme yearly means being 69° 48′ 47″ and 69° 37′ 52″. The resulting excess of 10″ for the winter months in the computed semi-annual means is so small, that the observations tend mainly to show that the effect of the sun's position is not clearly manifested by any decided variation in the dip. Deducing the intensity from the above elements, we obtain for the summer months the value 10·4136, whilst that for the winter months is 10·4128. The intensity of the earth's magnetic force would thus appear to increase with the sun's distance, but the difference is not large enough to have more than a negative weight in the question under discussion. This weight, moreover, is lessened by the slight uncertainty arising from the probable disturbing causes at the first magnetic station.

It is hoped that a second series of observations at the new station will throw greater light on the fact of the sun's influence on terrestrial magnetism, by either confirming the results obtained above, or by adding fresh weight to the conclusions arrived at by the President of the Royal Society.

"Preliminary Notice on the Production of the Olefines from Paraffin by Distillation under Pressure." By Dr. Thorpe and John Young.

"Contributions to the History of the Opium Alkaloids. Part I.—On the Action of Hydrobromic Acid on Codeia." By C. R. A. Wright, D.Sc.

Mathematical Society, March 9.—Mr. W. Spottiswoode, F.R.S., president, in the chair. Mr. C. R. Hodgson, B.A. Lond., was elected a member: and the following gentlemen were proposed for election:—The Hon. J. W. Strutt, Major F. Close, R.A., and Mr. James Stuart, Fellow and Assistant-Tutor of Trinity College, Cambridge. Two models of surfaces were exhibited by Prof. Henrici, which had been exhibited and described at previous meetings of the society. Prof. H. J. S. Smith, F.R.S., read a paper on "Skew cubics." The secretary (Mr. Tucker) then read a communication from Prof. J. Clerk Maxwell, F.R.S., entitled "Remarks on the Mathematical Classification of Physical Quantities." The classification referred to was founded on the mathematical or formal analogy of the different quantities, and not on the matter to which they belong. Thus a finite straight line, or force, or velocity of rotation, &c., are quantities, differing in their physical nature, but agreeing in their mathematical form. The two methods of classification, the one just referred to and the obvious classification founded on that of the sciences in which the quantities occur, may be distinguished by calling the first a mathematical and the second a physical classification of quantities. The secretary afterwards read a "Note on the History of certain Formulæ in Spherical Trigonometry," communicated by Mr. I. Todhunter, F.R.S., in which the formulæ usually known as Gauss' Analogies were claimed for Delambre. Dr. Hirst presented ten "Memoirs by M. Chasles" to the library of the society.

Entomological Society, March 6.—Mr. A. R. Wallace, president, in the chair. Baron de Selys-Longchamps was elected an honorary member, the Rev. T. A. Preston an ordinary member, and Mr. G. C. Champion a subscriber. Mr. Jenner Weir exhibited a small collection of butterflies from Madagascar. Mr. F. Smith exhibited two small branches of ash, from which a hornet had been observed in the act of removing the bark. He said that Réaumur had recorded a similar observation, and was of opinion that the insect was trying to reach the sap for food, and was not obtaining building materials. Mr. Smith further made some remarks on the disputed luminosity of Fulgora, and expressed himself in favour of the opinion that these insects are occasionally luminous.—Mr. Müller read notes on a gall-making Cecidomyia upon *Campanula rotundifolia*.—Mr. Lewis called attention to cases of antennal malformation in Lepidoptera.—Mr. Butler exhibited forms of *Cœnonympha Satyrion* from the opposite sides of the Gemmis, showing marked variation.—Dr. Sharp communicated notes on some British species of Oxypoda.—Mr. Lowne read a paper on "Immature sexuality in insects." The author thought that species sometimes originated from the maturity of the sexual organisation before the acquirement of adult characters; a conclusion he had arrived at in consequence of the early development of the organs in the embryo and larva. He further stated that, in his opinion, the larval and pupal conditions were probably acquired, and not direct, stages of development.—Mr. Briggs detailed experiments upon Lepidoptera, undertaken with a view of testing if the numerical proportion of the sexes, or sex itself, were dependent upon the food of the larva; the results negatived such suppositions.

Zoological Society, March 7.—Prof. Flower, F.R.S., in the chair. Mr. P. L. Sclater read the first part of a series of "Notes on rare or little-known animals now or lately living in the Society's Gardens."—These he had drawn up while engaged in preparing a new edition of the List of Vertebrated Animals in the Society's collection.—Dr. A. Günther read a List of the known Lizards belonging to the family *Sepidæ*, to which were added notes on some of the species.—A communication was read from Mr. F. Moore on some new species of Insects collected by Dr. John Anderson, during the recent expedition to Yunan.—A communication was read from Mr. A. G. Butler, containing descriptions of some new species and of a new genus of Diurnal Lepidoptera of the family *Pierinæ*, with a monographic list of the species of the genus *Ixias*.—Mr. A. D. Bartlett, Superintendent of the Society's Gardens, read notes on the birth of the Hippopotamus which had lately taken place in the Society's Gardens.

Hackney Scientific Association, February 28.—"The Fossil remains of the Mammalia found in the Lea Valley," by Mr. R. E. Olliver. Some extensive excavations in this district have recently exposed to view numerous beds of shell-marl, peat, loam, sand, and gravel, and, what is more interesting, have brought to light the remains of an ancient mammalian fauna. These remains chiefly belong to living species, as may be inferred by the deposit being assigned to the Post-Tertiary epoch. The mammalian remains which have up to the present time been determined are—Human remains, wild horse, red, fallow, and reindeer, elk, beaver, fox, wolf, goat, great fossil ox, Celtic shorthorn or small fossil ox, domestic ox, wild hog, gigantic round-antlered deer, mammoth, great cave bear, and the remains of an ox closely resembling *Bos longifrons*, which the writer strongly suspects to belong to a disputed series named *Bosfrontosus*. The fossil bones attesting the existence of these mammalia are found principally in the shell-marls and peat mosses, with the exception of the mammoth, cave bear, and great round-antlered deer, which are found in the grey sub-angular gravels, and rarely at a less depth than ten feet from the surface. The human remains, consisting of several skulls, possibly belong to that class named by Prof. Huxley the river-bed-skull. These skulls certainly belong to that period when the great fossil ox and elk were living, and not to that of the mammoth and cave bear. If, however, the evidence of the workmen is reliable, several skulls were found at a depth of thirty feet.—"A Catalogue of Variable Stars, with remarks upon their physical constitution."

Cambridge

Philosophical Society, February 27. — Communications made to the Society:—By Mr. W. H. H. Hudson, St. John's College, "On Observations made at San Antonio on the Solar Eclipse of Dec. 22, 1870." By Mr. Clifford, Trinity College, and Mr. Moulton, Christ's College, "On the Solar Eclipse of 1870." Mr. Hudson described the observations made at San Antonio during the eclipse, and with regard to his own with the polariscope came to the following conclusion: that observations of polarisation made with telescopes not specially prepared for the process are worthless, and that such polarisation of the corona as he was able to detect was due to the intervening atmosphere; appearances of polarisation being produced when light shines through a thin cloud. Prof. W. G. Adams exhibited with the lime light some photographs of the corona, and commented upon them. Mr. Clifford, who had been with the Sicilian party, described his experiences, and differed to some extent from Mr. Hudson as to the instrumental defects and the absence of polarisation: while Mr. Moulton corroborated Mr. Hudson's conclusions, and read a very interesting communication from Father Perry, summing up the results of the spectroscopic observations at the various stations.

Winchester and Hampshire

Scientific and Literary Society, February 22.—The Rev. G. A. Seymour, M.A., and Beresford N. Earle, M.A., M.B., Fellow of the Cambridge Philosophical Society, were elected members. There was a good show of objects of interest in natural history, amongst which, exhibited by the president, was a collection of British land and fresh water shells, and a specimen of recent chalk dredged by Dr. Carpenter from a depth of 2,435 fathoms in the Atlantic. Microscopic slides of the same were exhibited by Mr. F. I. Warner, showing the unbounded amount of animal life at that enormous depth. Dr. Heale showed, under the microscope, the curious movement of the spiral vessels of the Collomia seed.—The Rev. W. Awdry, M.A., read a learned and interesting paper entitled "Some Ideas worked out in Gothic Architecture."

Glasgow

Geological Society, February 2.—Mr. John Young, V.P., in the chair. "On the Boulders found in Cuttings on the Beith Branch Railway, considered in Relation to their Parent Rock; with observations on the local character of the Boulder Clay," by Mr. Robert Craig. The lines of railway referred to, now in course of formation, run nearly south-east from Beith, changing as it reaches Waterland to direct east. The striations upon the glaciated rock-surfaces in the district have a general bearing, per compass, of nearly N.E. to S.W.; the line accordingly, at its western terminus, crosses them almost at right angles. The cuttings run nearly parallel to the southern termination of that range of trap hills which extends from Gleniffer to Beith, and at the distance of little more than a mile from it. The carboniferous strata crop out along the southern boundary of this trap range, and consequently about a mile to the north of the railway. In the trap range four well-marked varieties of porphyrite occur, which, with the easily distinguished beds of the Carboniferous limestone, gave the geologist an opportunity of classifying the boulders and tracing them to their source with an exactitude not always attainable. Mr. Craig then referred to the boulders from a distance, consisting of Old Red sandstone, clay slate, mica and chlorite schists, quartz, gneiss, granite, found associated and intermixed with the local boulders. Of these the Old Red sandstone figures highest, and consists of two varieties—one of a highly red colour, the other of a dark grey. Both of these are found *in situ* along the shores of the Firth of Clyde, and in other parts of Scotland, flanking the Highland mountains. He considered these erratics might be accounted for without either drift-ice or submergence, simply by the operation of land-ice, or glaciers, bearing these fragments in passing from the Highland mountains, whose tops, many of them, would be 1,000 feet above the ice, even allowing the sheet to be 2,000 feet thick. It was well-known that ice, in moving over uneven ground, became rent into fissures and crevasses, down through which the stones it was carrying on its surface found their way to the bottom, and thus became mixed up with the "foot-board moraine." In further proof of this, he gave the highest points above the cuttings whence the local boulders could have been derived, showing that these boulders could not have fallen upon the surface of an ice sheet thicker than 200 feet; and, besides, that many of them came from beds scarcely higher than the position in which they are now found. The perfectly local character of the boulder-clay, with the exception of the erratics, he thought was demonstrated; and from some sections in which he had followed the course of the ice-stream, he found that there was a change in the boulders every three to five miles, less or more, according to the roughness or evenness of the ground.—A collection of phosphates from Charleston, U.S., was exhibited by Mr. Potts and Mr. Naismith, together with some large fossil teeth, vertebræ, &c., from the same locality. Mr. Potts stated that large quantities of these phosphates are being used in America, and also imported into this country, for the manufacture of artificial manures. The deposit from which they are taken is found along the banks of many of the rivers in South Carolina, and immediately under the surface soil of the land lying between; and is supposed to underlie a large portion of the coast and sea-island region of that part of America. It consists of layers, varying six inches to several feet in thickness, of irregularly rounded nodules, mixed up with an immense quantity of bones—ribs, vertebræ, tusks—of various species of animals, all more or less petrified. The nodules yield 50 to 60 per cent. of bone phosphate; while from some of the bones as much as 80 to 85 per cent. of this fertilising substance had been obtained. The Chairman said there could be no doubt this remarkable deposit of phosphates belonged to the Tertiary period; and probably its earlier division, the Eocene. The Tertiary formation is largely developed along the southern coast of North America, stretching in a belt of considerable breadth from North Carolina to the Gulf of Mexico, and leaving the coast-line only at the delta of the Mississippi. The whole series of fossils, like those before them, indicated a much warmer climate than now prevailed in that part of the world, and showed that the waters of the sea were teeming with large and powerful forms of life.

DUBLIN

Royal Dublin Society, February 20.—Dr. Croker King in the chair. Prof. Macalister delivered a discourse "On Recent Advances made in Comparative Anatomy." He alluded to the investigations of Kowalersky published in the Transactions of the Imperial Academy of St. Petersburg as to the relationship that exists between the Ascidians and Vertebrates; also to the many recent investigations into the comparative myology of the upper and lower extremities, and alluded to a very simple yet neat nomenclature of the muscles of these parts.

Natural History Society, March 1.—Rev. Dr. Haughton, F.R.S., in the chair. A paper was read by Mr. G. H. Kinahan on ferns observed in Yar or West Connaught, the part of Co. Galway that lies west of Loughs Mask and Corrib, with localities of a few rare ferns in south-west Sligo.—Mr. W. Andrews read a paper, "Notes on the Ichthyology of the South-West Coast of Ireland." It is always of interest to bring to notice any new facts either in the zoology or botany of a country or district, but more especially so when any discovery can be recorded which presents new features of animal or vegetable life, the existence of which had not been previously known. The chief remark conveyed in this paper is with reference to the capture in January last on the south-west coast of several specimens of a fish of extremely rare occurrence, the *Trichiurus lepturus*; the occurrence of *Centrolopus pompilus* in numbers off the coast of Dingle was also mentioned, and also that of a fine specimen of the tunny caught in Brandon Bay, October 1869. The author gave many details as to the structure of the *Trichiurus*, and concluded with stating that he felt confident that we have not yet gleaned the extent of interest that exists in the marine zoology of our shores, or of the deep water of our coasts.

Royal Zoological and Geological Societies of Ireland, March 8.—Prof. Hull, F.R.S., in the chair. The Rev. Dr. Haughton, F.R.S., read a paper on the Mechanism of Flight in the Albatross (*Diomedea exulans*), considered in relation to its muscular anatomy.—Prof. Macalister read a paper on some Parasites found on Animals from the Dublin Zoological Gardens.—Rev. Dr. Haughton made some remarks on the recent death of four lion cubs in the Society's gardens.—Prof. Traquair exhibited a collection of carboniferous ganoid fishes from Wardie, in Scotland.

HALIFAX, NOVA SCOTIA

Institute of Natural Science, February 13.—J. M. Jones, F.L.S., President, in the chair. Dr. Honeyman, F.G.S., read a paper, "On the Geological Formation of the Picton Coal Field," which was a continuation of his record of geological discovery in Nova Scotia, delivered at the November meeting of the Institute. The present paper showed that the Devonian was absent, and that the underlying formations were Upper and Middle Silurian, arranged in several anticlinals, synclinals, and monoclinals. The lithological character of these formations at the time of the deposition of the overlying Carboniferous strata was as it now exists. The strata were more or less metamorphic, and the system of folds was, as has been indicated, and were washed on the north, south, and west, by the seas of the Carboniferous period. Lower Carboniferous conglomerate and grit succeeded by gypsum were deposited on Lower Helderberg strata (Upper Silurian), highly fossiliferous at Irish Mountain. Argillaceous shales with overlying limestones were formed on Lower Helderberg strata (very fossiliferous), and rather higher in the series than the strata of Irish Mountain. In Springville there are two localities where the Silurian strata on the same horizon as Irish Mountain (possibly a little lower) are overlaid *directly* by Lower Carboniferous limestone. Farther up the river there are three localities where Lower Carboniferous limestone overlies Silurian strata; in two cases, a breccia is formed with the limestone and metamorphic slates belonging to the lowest part (or nearly so) of the Middle Silurian age. In the remaining case, in the river at Pleasantville a great band of Lower Carboniferous limestone lies unconformably on Lower Helderberg or Upper Silurian, highly metamorphic. In Cross Brook, Irish Mountain, Lower Carboniferous sandstones with limestone overlie Clinton strata of the Irish Mountain Silurian series with fossils, and also the denuded axial greenstone. At McLellan's Brook, Lower Carboniferous grits succeeded by limestone come up against the back of Clinton strata of the other side of the Irish Mountain anticlinal. At the lowest falls of Sutherland's River, Lower Carboniferous conglomerate comes up against the back of the Medina slates, metamorphic, apparently non-fossiliferous of Wier's Mountain of the monoclinal series. Higher up Sutherland's River at McPherson's is the passage from the Picton into the Merigomish Carboniferous area. Here Lower Carboniferous grits containing a brine spring come up against the back of Medina strata, very little altered with characteristic Petraia and Lingulæ. These are succeeded by Clinton shales with cone in cone concretions and lingulæ nodules in abundance. In this district are two mountains with porphyry. Conglomerate, grit, argillaceous shale, and limestone of Lower Carboniferous age, have thus been formed contemporaneously. Then succeed alternations of sandstone and limestone and gypsum. Thus are formed limited areas of limestone in different geological positions and entirely disconnected. The order of formation of the representative beds of limestone appears to be as follows:—1. The Black pyritiferous limestone in closest contact with the Lower Helderberg slates having obscure brachiopoda visible, particularly by weathering. 2. The Lithostrotian limestones of Springville and McLellan's Brook. 3. Limestone strata with intercalary shales, below Springville Factory on the river, highly fossiliferous, containing Orthocera, Bellerophon, Gasteropoda, Conchifera, Crinoidea, and Fucoids. 4. Thick bedded limestone formed of an agglomeration of minute Conchifera and Crinoidea. Above this are strata with teeth of cochliodus. This limestone appears to be of the same age as similarly formed limestones on the West Branch having Conularia. In the Silurian formation on separate anticlinals are—1. An apparently valuable bed (?) of limonite. 2. A bed of fossiliferous iron ore of considerable thickness. 3. Pockets of specular iron ore. These, although separated, are of the same geological age—Clinton. The Medina and Lower Helderberg strata of the area examined, in their passage across rivers and brooks, form numerous waterfalls, some of which are mill sites. Fine exposures of Lower Helderberg fossiliferous strata in McLellan's Brook and Sutherland's River, form the foundation of a mill dam in the brook and formidable rapids in the river. The Picton Coal Field is well known through the writings of Dawson and others. Its thick coal seams have been represented by columns in the International Exhibitions of London, 1862, Dublin, 1865, Paris, 1867. In the discussion which followed, the President called attention in an interesting zoological fact mentioned by Dr. Honeyman to one part of his paper, viz.—the common cattle of the neighbourhood in which he had found a brine spring, resorting to such fountain and greedily drinking its waters. The same habit was also to be observed in the wild buffalo of the western prairies, which annually resorted to certain well-known "salt licks" for a similar purpose.

BERLIN

Berlin Society of Anthropology, Ethnology, &c.—Prof. Virchow continues (*Zeitschr. für Ethnologie*, 1870, vi.) his communications on the subject of the urns with sculptured faces, already treated by himself, by Nilsson, and by Kupfer; and also read a paper on "Settlements belonging to the Stone age in Nieder-Lausitz," &c., and a third on a visit to the Westphalian bone caverns. Among the same transactions may be noted a letter from Fisch on the *Framea*, in which he derives the word from the old Gothic *fram* (the English *from*) and explains to mean a weapon thrown *forwards*,—*telum missile:* the subject was again discussed at a late sitting (*ib.* iv. p. 347). A paper was read by V. Martens on the implements used by the Dyaks of the interior of Borneo: a letter from Kupfer on the remarkable vases with human faces which were the subject of Virchow's communication to the same society last March; and a long paper, with woodcuts, on the vitrified stone sites of Oberlausitz by Prof. Virchow, which shows with what accustomed ability the great pathologist pursues the inquiries which amuse his holidays.

PARIS

Academy of Sciences, March 6.—M. Henry Sainte-Claire Deville proposed to his colleagues to enlarge the scope of their proceedings, and to deliberate upon any subject relating to social matters which can be promoted through the instrumentality of science. This idea was warmly advocated and supported by M. Bouley, M. Dumas, and others, and met with only one opponent, M. Combes, general inspector for Ponts-et-Chausées, who said that such a step was contrary to the rules of the Academy, and that the Academy besides had no right to pronounce on a communication from its own members. But ultimately the discussion of the proposition was referred to a secret committee, which is to be held probably next week. This sitting was rife with discussion.—M. Faye having referred to a special committee the project of a railway to be constructed between America and Europe through the Aleutian Islands, General Morin protested, saying it was merely wasting time to refer such wild schemes to members, and that the committee was, at all events, not bound to give any opinion at all. In spite of this protest, M. Faye referred the communication to a member in order to know from him if it was worth being sent before a special commission.—M. Delaunay and M. Bertrand disputed what was the precise opinion of M. Hopkins on the thickness of the solid crust of the earth. M. Delaunay said moreover that calculations proved it had no influence on the revolution of the earth, as no movement of the internal fluid could possibly have any effect whatever.—M. Bouley declared that the flesh of animals infected with the cattle plague was not unwholesome for food. It is true that such flesh is served out to poor people supplied from municipal benevolent institutions. But such is not the view taken by the paying public, as the purchase of beef is falling, and the sale of mutton or pork increasing daily. The rinderpest is raging so severely in the herds destined for the revictualling of Paris, that very often carts loaded with carcasses are seen passing through the streets of the city.—M. Janssen was present at the sitting, and he is going to London, where he will arrive by the end of the present week. Many of the *francs-fileurs* have resumed their seats without any remark having been passed upon them. M. Becquerel the elder, the celebrated electrician, died in Normandy during the investment of Paris. He was about 80 years of age. The water-tubs and towels disposed in case Prussian shells should set fire to the building have not yet been removed from the hall.

BOOKS RECEIVED

ENGLISH.—The Natural History of the Strait of Magellan: R. O. Cunningham (Edmonston and Douglas)—The Story of Aristæus and his Bees: R. M. Millington (Longmans).—A Few Poems: E. Smith (Dunn and Fry). - The Ancient Geography of India: A. Cunningham (Trübner and Co.).—The Chronological History of Animal Plagues from B.C. 1490 to A.D. 1800: G. Fleming (Chapman and Hall).

FOREIGN.—(Through Williams and Norgate)—Die elektrische Doppelhebel: J. N. Czermak.—Untersuchungen aus den Institute für Physiologie u. Histologie in Graz 2tes Heft: A. Rollett.—Echinologie Helvétique: Désor et de Loriol.

DIARY

THURSDAY, MARCH 16.

ROYAL SOCIETY, at 8 30.—Description of Ceratodus, a Genus of Ganoid Fishes, recently discovered in Rivers of Queensland, Australia: Dr. Günther, F.R.S.—On the Formation of some of the Sub-axial Arches in Man: G. W. Callender.

SOCIETY OF ANTIQUARIES, at 8.30.—On Photographs of Armenian Antiquities: Captain Lynch.—On an Undescribed Expedition to Britain in the Reign of Augustus: W. H. Black, F.S.A.—On certain inscribed leaves of lead in the British Museum: W. De Gray Birch.

LINNEAN SOCIETY, at 8.

CHEMICAL SOCIETY, at 8.

ROYAL INSTITUTION, at 3.—Davy's Discoveries: Dr. Odling.

LONDON INSTITUTION, at 7.30.—On the Colonial Question: Prof. J. E. Thorold Rogers, M.A.

FRIDAY, MARCH 17.

ROYAL INSTITUTION, at 9.—On the Eclipse: J. Norman Lockyer, F.R.S.

ROYAL COLLEGE OF SURGEONS, at 4.—On the Teeth of Mammalia: Prof. Flower.

SATURDAY, MARCH 18.

ROYAL INSTITUTION, at 3.—Spirit of the Age: Mr. O'Neil.

SUNDAY, MARCH 19.

SUNDAY LECTURE SOCIETY, at 3.30.—The Total Eclipse: J. N. Lockyer.

MONDAY, MARCH 20.

ANTHROPOLOGICAL INSTITUTE, at 8.—Adjourned Discussion on the Racial Aspects of the Franco-Prussian War.—On the Migrations of the Georgians, Circassians, and Amazons, and their connection with the Tibeto-Caucasian Race: Mr. Hyde Clarke.

ENTOMOLOGICAL SOCIETY, at 8.—On Additions to the Atlantic Coleoptera: Mr. Wollaston.

VICTORIA INSTITUTE, at 8.—On some Curiosities of Ethnology:—Rev. J. H. Titcomb.

LONDON INSTITUTION, at 4.—On Astronomy: R. A. Proctor, F.R.A.S. (Educational Course.)

ROYAL COLLEGE OF SURGEONS, at 4.—On the Teeth of Mammalia: Prof. Flower.

TUESDAY, MARCH 21.

ZOOLOGICAL SOCIETY, at 9.—Report on additions to the Society's Menagerie during the month of February 1871: P. L. Sclater.—On the Birds of Santa Lucia, West Indies: P. L. Sclater.

STATISTICAL SOCIETY, at 7.45.—On Statistical Returns required by Parliament: Mr. Purdy.

ROYAL INSTITUTION, at 3.—Nutrition of Animals: Dr. Foster.

WEDNESDAY, MARCH 22.

GEOLOGICAL SOCIETY, at 8.—On the Passage beds in the neighbourhood of Woolhope, Herefordshire, and on the Discovery of a new species of *Eurypterus*, and some new land-plants in them: Rev. P. B. Brodie, M.A., F.G.S.—On the Cliff-sections of the Tertiary beds west of Dieppe, in Normandy, and at Newhaven, in Sussex: W. Whitaker, B.A., F.G.S.—On New Tree-ferns and other Fossils from the Devonian: Prof. J. W. Dawson, F.R.S.

SOCIETY OF ARTS, at 8.—On Drill, the Complement of the Present School Teaching: Major-General Eardley-Wilmot, R.A.

ROYAL COLLEGE OF SURGEONS, at 4.—On the Teeth of Mammalia: Prof. Flower.

THURSDAY, MARCH 23.

ROYAL INSTITUTION, at 3.—Davy's Discoveries: Dr. Odling.

BOTANICAL MUSEUMS

THE keeping up at the public expense of two great rival National Botanical Establishments, the one in London the other at Kew, in a state of continual competition with, instead of aid to, each other, whilst a third independent one, also national, may occasionally come into collision with one of them, seems to be a waste of public money, without any advantage to science or to the public, and attended with many inconveniences.

At the same time two great Botanical Museums and Herbaria, the one in connection with the Natural History Museum in London, the other with the Botanical Gardens at Kew, working in harmony with each other, but for different purposes, and separated by a clear line of demarcation from the Economic Museums of South Kensington, would always be productive of great benefit to science and gratification to the public.

The main purposes of a Botanical Museum and Herbarium may be said to be threefold—the Study of plants, their Comparison, and their Exhibition; the first purely scientific; the second sometimes scientific, sometimes popular, the third chiefly popular. For the first, Kew affords incomparable advantages, the second and third would probably be best promoted in town, provided always that the two establishments work in perfect harmony, with unity of plan, both in general arrangements and in matters of detail.

1. For the close Study of plants,—the only sound foundation upon which the science of Botany can be usefully established,—for their accurate determination and practical classification, the requisites are: that the herbarium should be as rich as possible not only as to genera and species, but as to variations of all sorts and repetitions of the same form from different localities and stations; that the herbarium should be a single one, the geographical arrangement being kept in subservience to the scientific classification, and without any detached smaller herbaria, except such definite historical ones as only require occasional reference like the books of a library; that there should be good accommodation for the sorting of unnamed collections and fresh arrivals, ample means for the dissection and examination of specimens not only by the staff of the establishment, but also by scientific botanists in general, who, under special regulations, are allowed to work in the herbarium, and storerooms for duplicates required for exchanges, &c.; that there should be in the same suite of rooms as the herbarium a botanical library, as complete as possible, and a series of drawings of plants, also as complete as possible; that the herbarium should be in close connection with the national collection of living plants; and that it should be under the keepership of a resident scientific botanist, with the requisite staff of scientific assistants. All these essentials are at present afforded by the Herbarium at Kew, in a degree far beyond what can be met with in any other establishment at home or abroad.

2. The Comparison of plants—their practical and rapid determination without dissection, or the obtaining a general idea of natural groups from the Order down to the Species, as required by the general naturalist, by the follower of sciences in immediate connection with botany, especially the palæontologist, or by the mere amateur—demands a very different herbarium and museum from that of the working establishment. It should consist of accurately named select specimens, representative of as many species or well-marked varieties as possible, without duplicates in the same collection. It might be advantageously divided into two separate collections, one a general typical one, the other geographical. Separate collections also of leaves and of fruits, all accurately named, and so arranged as to enable them to be rapidly glanced over, would be most useful to the palæontologist. Such a museum would require no space for the sorting and determining of unnamed collections, nor for the storing of duplicates, and no provision for the dissection of specimens except for the personal use of the keeper and his assistants, being supplied only with such tables or other appliances for consultation as are usually required in a library. Its library should be extensive, but select rather than complete, and should include various palæontological and other works on kindred sciences, not required in the working herbarium. It should be in near connection with the National Museums for kindred sciences, especially with other palæontological collections. The keeper should be a scientific geologist, as well as botanist, and would require probably but one scientific assistant.

3. The Exhibition of plants, or rather of botanical specimens, is for the purpose of exciting the interest and gratifying the curiosity of the general public, and for this a herbarium, strictly so-called, is of no use—the public would never look beyond the outside of the cases. It requires the display in glass cases of such selected specimens of plants or their parts, accompanied by explanatory notes and diagrams, as may give at a cursory glance some idea of the characteristic features of the principal groups of plants; and to these might be usefully added a few specimens remarkable only for their beauty or singularity, for the purpose of attracting the eye, and riveting the attention of the observers. As these specimens, when once placed, require no further handling, and no care beyond the inspection of an ordinary assistant, and as the objects of visitors to such a Museum would be much promoted by a ready connection with the public Museums in other branches of natural history, it would seem highly advantageous that it should be attached to the herbarium for comparison, and form part of the London Botanical Museum, in close proximity to the National Museums of Zoology and Geology.

We have now no Museum in any degree adequate to these two purposes of Comparison and Exhibition, but were the two national collections of the British Museum and Kew combined, all unnamed plants, duplicates, and specimens of interest only to the scientific botanist, removed to Kew, and in return, from the immense mass of materials there accumulated, the London herbaria completed by accurately-named representative specimens, there would result collections richer in species and far more useful than any actual Continental ones; and as science advances and materials increase, these collections would be constantly kept up to the mark by named specimens from Kew, whilst their scientific arrangement and application to use could not be under a direction better qualified than that of the recently-appointed keeper of the botanical department of the British Museum.

In this London Botanical Museum would be also appropriately placed various pre-Linnean and other botanical collections, having only a historical or other adventitious interest, but there would be little use in attempting there anything corresponding with the Museum of Economic Botany, which has acquired so much importance, and is so well placed at Kew. That could only come into competition with the economic collections at South Kensington, but all prejudicial collision between the two is clearly avoided, and each one will increase its own practical utility by strictly adhering to the rule that at Kew the products are arranged according to the plants they are derived from; at South Kensington, according to the uses they are put to.

POPULAR ORNITHOLOGY

Cassell's Book of Birds. Translated and adapted from the text of the eminent German Naturalist, Dr. Brehm, by Thomas Rymer Jones, F.R.S., Professor of Natural History and Comparative Anatomy in King's College, London. 400 woodcuts and coloured plates. Parts I.—XIV. (London: Cassell, Petter, and Galpin.)

PERSONS wishing to be misinformed on the subject of Ornithology should obtain and read the "Book of Birds" now in course of publication by Messrs. Cassell, Petter, and Galpin, and recommended by them to "everyone who wishes to know all that is known about birds." The advertisement whence these words are quoted also tells us that the work, when completed, is to contain "upwards of 400 engravings, embracing every species of birds known to exist;" but as on a moderate computation some 12,000 species of birds have been described, it is pretty clear that to fulfil that promise each engraving should represent 30 species or thereabouts. The most cursory inspection of the portion published (and we have the fourteenth part lying before us) will show that nothing of the kind has been done, and that many groups are left without an illustration at all.

Furthermore, the work is announced as "translated and adapted from the text of the eminent German naturalist, Dr. Brehm, by Thomas Rymer Jones, F.R.S., Professor of Natural History and Comparative Anatomy in King's College, London," a collection of assertions which we take the liberty of questioning. We are aware of the recent existence of no fewer than four German naturalists of that name, all of them, we believe, entitled to the doctorial prefix. Of these four, which is the one whose labours are chosen for the exercise of Prof. Jones's industry in translation and ingenuity in adaptation? *The eminent* Dr. Brehm ought, of course, to be the answer; but then the most "eminent"—that is the best known and most prolific writer of the four—was Dr. Christian Ludwig Brehm, who, having attained great notoriety as a "splitter" of species, died at an advanced age some half-dozen years since, leaving two of his three bedoctored sons behind him. Now, Dr. Brehm, the father, among his many works certainly never published one which could be "adapted" to the form of Messrs. Cassell's "Book of Birds:" nor did Oscar Brehm, the son, who died in his father's lifetime. The question is therefore narrowed to the works of the survivors. Of these Dr. Reinhold Brehm has contributed several ornithological papers to journals, but none of any great importance, and there is no need to accredit him with the authorship of any work at all resembling the present. It seems therefore that Dr. Alfred Brehm must be in the eyes of the English publishers and translator "the eminent Dr. Brehm." We are inclined to believe that the production we are now reviewing is his offspring, whether he deserves to be called "the eminent German naturalist" or not, and that it has not hitherto been printed, since an examination of his work, "Das Leben der Vögel," from which some of the illustrations in the present book are taken, fails to show that its text furnishes the groundwork for "Cassell's Book of Birds."

Having thus justified, as we hope, our doubts as to the "Book of Birds" originating from "the eminent Dr. Brehm," we must further express our doubts as to Prof. Jones being the translator and adaptor of it from the German of another naturalist of the same name. Here our doubts, it may be thought, do not rest upon so satisfactory a base; but the meritorious work by which Prof. Rymer Jones is best known, his "Outline of the Animal Kingdom," shows that its author is gifted in no common degree. The character of Professor Jones's volume was and is caution and accuracy, the character of the "Editor's Introduction" to the "Book of Birds" is the reverse. Here is an example. Its writer says (p. 17): "In order to render the following account of the structure of a bird's skeleton intelligible to the non-scientific reader we have delineated that of the Goose," and a reference is added to "Fig. 12," which faces these words. Now we scarcely expect that we shall be believed, but it is an undoubted fact that there is no figure of a Goose's skeleton at all, and that "Fig. 12" represents the skeleton of a bird so entirely different as a Pigeon; while so far from the inference being true that the editor has "delineated" the subject for the express purpose of enlightening his readers, we must declare that the woodcut in question is a very bad enlargement of what has been for years a stock-figure in anatomical handbooks. We do not pretend to know its origin, but we have now before us a far better copy of it in a Swedish work,* and it has been repeated in many other books. That Prof. Rymer Jones has been guilty of such a blunder, to say nothing of such a *suggestio falsi* as this, we hold to be incredible. Again we have close by another woodcut (p. 22), which we are told represents "A young chicken shortly after its escape from the egg." Now we cannot believe that such an explanation was written by Prof. Rymer Jones, for he must well know the figure to be that of a young Blackbird assuming the first or nestling plumage, as it is rightly said to be in the "Catalogue of the Physiological Series" of the Museum of the College of Surgeons, where (vol. ii. Part II. p. 312, pl. xlv. fig. 4), the original of the woodcut may be found. Those who can believe that Prof. Rymer Jones does not know the difference between a Goose's skeleton and a Pigeon's, and between a Chicken newly hatched and a Blackbird just about to leave the nest, may believe it, we unhesitatingly declare we do not.

But it might be urged that all these matters are of little

* "Grundlinier till Zoologiens Studium," af Karl Torin. (Stockholm, 1870) 3d ed. i. p. 87.

consequence; that 12,000 birds obviously cannot be figured in 400 engravings, and the statement was only intended to mean that the work is profusely illustrated; that English readers do not care a button whether there are as many Brehms as birds, or what books they write; and that diabolical agency in the press may blunder as to woodcuts or their explanations. Suppose we grant all this, and consider the rest of the work. We have expressed doubts as to the authenticity of the "Editor's Introduction," but even if they are rightly founded, the affair may be condoned should the translator and adaptor have performed his task well. We imagine that the first duty of a translator is to give an exact rendering of every phrase or name in the original, and it becomes necessary to see how far this has been done in the present instance. If there is a foreign bird well-known in this country, it is the common Grey Parrot—here we are taught to call it the "Jako" (p. 35), which may well be its German name but is not an English one. So also the great South-American group of Tanagers are throughout (pp. 150-155) "Tangaras." A similar case is that of the Serin, which is left (p. 106) under its Teutonic appellation of "Girlitz," which common German idiomatic term is comically rendered (p. 107) "a little pair;" and the British public has to find out as it best can that by "Tree-Falcon" (p. 305) is meant our well-known summer visitant the Hobby, though under the latter name it has flourished for hundreds of years. Indeed, the translator's ignorance of his subject is manifest on almost every page, but nowhere is it so remarkably displayed as when he introduces (p 50) the word "Dronte," without the slightest apparent perception that by it is meant our old friend, the Dodo! Further proof of his incompetency for his task is shown by the mistakes (which cannot all be misprints) in the names of naturalists; thus we have "Jerdan" (p. 30) for Jerdon, "Speke" (p. 39) for Spix, "Boja" (p. 126) for Boie, and "Nardoi" (p. 300) for Nordvi. That a corresponding indifference to the niceties of scientific nomenclature should be exhibited is, of course, to be expected; but, setting aside such untechnical forms as "*Corys alauda arborea*" (p. 204) and "*Cecropis-Hirundo-domestica*" (ii. p. 105), we can hardly think that Dr. Alfred Brehm could have ever said that Linnæus named a bird *Derotypus accipitrinus* and *Derotypus coronatus* (p. 42), and we must suppose that the original sentence has been misunderstood.

Another instance, if another be wanted, to prove the inaptitude of the translator for his work, is the confusion existing in his mind between words like "variety," "race," "tribe," "family," and even "order." However much naturalists may differ as to the limits or value of the groups thus designated, all are expected to have clear notions as to what the terms mean. The translator of the "Book of Birds" jumbles them together, and thus raises fresh doubts as to his identity with Prof. Rymer Jones. We have "varieties" spoken of (p. 92), where species are clearly meant; "race" (p. 55 and p. 150), when something at least as comprehensive as a family is intended; "tribe" (p. 47 and p. 122) without any definite meaning at all; and "family" (p. 43 and ii. p. 136) in a sense as obscure; while "order" is used so vaguely that in one place (p. 23) it includes all the parrots and some other birds, which last, when they come to be described (p. 83) are spoken of as forming an "order" of themselves, so that we have an "order" within an "order," whereat our reader will probably exclaim "Disorder!" Dr. Alfred Brehm may have some queer ideas as to classification (of which more immediately), but we feel sure he never committed such a high crime and misdemeanour as this.

Having thus noticed some of the shortcomings of the translator, we must say a few words on the author's treatment of the subject. We have just referred to his ideas on classification, but it is not easy to ascertain what they really are, for no scheme of arrangement is given. Enough however is to be gathered to show that they are somewhat peculiar if not original. We do not quarrel with him on this account. In the present state of ornithological science, its teachers, as well as its students, may well be pardoned for not adopting any plan already promulgated; but in a work intended for "everyone who wishes to know all that is known about birds," it is only reasonable to expect that the projects of prior systematists should receive some attention, and due cause shown why such and such arrangements are inadmissible or the contrary. Now we cannot find anything of the sort here. It is true that the author begins by remarking (p. 23) that it is usual in most ornithological works to place the Vultures first, but they are "the most disagreeable and least intelligent of the race" (admirable and philosophical reasons for deposing them!), and he recognises in the Parrots the "qualifications most fitted to entitle them to take precedence." For them accordingly he constitutes a "distinct order under the quaint but expressive names of Crackers (*Enucleatores*)"—we will not copy the printer's bad spelling of the last word. Many ornithologists will so far agree with Dr. Alfred Brehm, but we read on, and to our surprise find that this order is "by no means limited to the parrots; it includes various other seed-eating birds, chiefly belonging to the passerine tribes, the resemblance of which to parrots has been in some cases generally acknowledged in selecting the names ordinarily conferred upon them. Thus, the Crossbills have long been known in Germany as the Fir-tree parrots, and, on the other hand, the epithet of Sparrow-parrots, applied to some races of climbing birds, clearly shows the relationship that exists between these generally dissevered groups." Yet a few words more are needed before we conclude.

There is Science, and Science falsely so called. It is a rank offence to give the stone of science falsely so called, instead of the bread of true science, and this is what all concerned in the present work must be held to have done, while to back up the imposture by assertions which are palpably or presumably untrue, is an aggravation of the crime, and like all crimes, its commission is a mistake. There is no more erroneous belief than that a book to be popular cannot be scientific, for numerous are the scientific books which have attained to a high degree of popularity. But scientific books are under a heavy disadvantage when they have to struggle for existence amid a growth of specious pretenders. The young beginner full of enthusiasm knows not at first to distinguish the wheat from the tares which surround it. The duty, therefore, of everyone who does know the difference, is to point out and bind the tares for the burning, and in doing this he must not shrink from expressing his opinion of those who sow them. We have heard it said that it matters not how rubbishy a book of Natural History may be, for, provided that it be of such a kind as to command a large sale, it must foster a taste for the subject among the million. This is a most pestilent doctrine. If the tares occupy the ground, how can the wheat grow? and the publication of every book of spurious science precludes the publication of a really scientific book on the same subject.

OUR BOOK SHELF

The Arts in the Middle Ages, and at the Period of the Renaissance. By Paul Lacroix, Curator of the Imperial Library of the Arsenal, Paris. (London: Chapman and Hall, 1870.)

A TASTE for art usually comes to us somewhat late in life, because, in nine cases out of ten, the taste is not cultivated or developed till long after school life. We have, in fact, no regular art education in this country, although endeavours are being made at South Kensington to form Art Schools, and to accumulate art students. A love for high art is certainly more common in France and Italy than in England, and this is partly accounted for by the fact that some education in the first principles of the arts is given in all the government schools and colleges. The work before us is well calculated to foster such tastes. It discusses not alone the principal arts:—" We pass in review," says M. Lacroix, "all the Arts, starting from the fourth century to the second half of the sixteenth. Architecture raising churches and abbeys, palaces and public memorials, strong fortresses, and the ramparts of cities; sculpture adorning and perfecting other arts by its works in stone, marble, bronze, wood, and ivory; painting, commencing with mosaic and enamels, contributing to the decoration of buildings jointly with stained glass and frescoes, embellishing and illuminating manuscripts before it arrived at its highest point of perfection, with the art of Giotto and Raphael, of Hemling and Albert Dürer; engraving on wood and metal, with which is associated the work of the medallist and the goldsmith; and after attempting to touch upon playing cards and niello-work, we suddenly evoke that sublime invention destined to change the face of the world—Printing." Although M. Lacroix speaks above of passing in review *all the arts*, we notice at once that he has mixed up the fine and the useful arts, and omitted some of each of them. Moreover, he has chiefly discussed what we call the "decorative arts." Poetry is omitted altogether, and the only account of music is given under the heading "Musical Instruments."

The book itself is gorgeous. It is well printed, and is full of good engravings and woodcuts. Moreover it contains nineteen excellent chromo-lithographs, by Kellerhoven, the most notable of which are the sixth ("Biberon of Henri Deux Faience") and the thirteenth ("The Dream of Life," a fresco by Orcagna). We have no book in our own language which satisfies the want, which must so often have been felt, of a work of this nature. It is a positive art-educator, and what with the appointment of Professors of the Fine Arts at Oxford and Cambridge, and the appearance of a few works of this kind, we may hope before long really to possess in this country some critical taste for all that is beautiful in art.

G. F. R.

Descriptive Travel and Adventures; or Hubert Preston Abroad. By Catharine Morell. Edited by J. R. Morell, formerly one of Her Majesty's Inspectors of Schools. (London: T. Murby.)

WE hope this is not a sample of "The Consecutive Narrative Series of Reading Books," of which it appears to be the 6th volume, for the sake of the unfortunate youths in whose hands they may be placed. We scarcely know a book which we should take greater pains to keep out of the hands of young people eager for knowledge. It is full of the grossest and most palpable blunders. We will quote the three first we came across, giving chapter and verse, as we hardly expect to be believed without affording our readers the opportunity of verifying our quotations for themselves, if they wish to. When we read (Chemistry, p. 83) that "quicklime is simple carbonate of lime taken from the limestone of your mountains!" we thought we had pitched upon a curious slip of the pen; when we found that "marsupials," (which, by the bye, are known as being animals *that jump instead of run*) "are peculiar to Australia," and "*the tiger peculiar to the New World!!*" (Growth of Plants, p. 173) we opened our eyes with astonishment; and when we were told that *the elephant chews the cud!!!* (The Elephant, p. 197), we closed the book in disgust. Surely any boy on the lowest form of any school which the gentleman who edits the book "formerly inspected," would have set him right on all these points. Seriously, it is very sad that at this time of day it should be found possible to circulate such rubbish under the name of instruction in science. If this is what is to come of inspecting schools, the less we have of it the better, till we have trained up a staff of inspectors acquainted with at least the rudiments of science. B.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Teaching of Science

I AM the principal of a private school. I have long taken an interest in science, and have, by proceeding very gradually and cautiously, succeeded in making Scientific Teaching for a limited time in the week a part of the regular school course. There are many more difficulties, however, in the way of this than some of your off-hand devotees of science seem to be aware of.

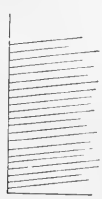
Not the least of these is the decided opposition of some parents, who object altogether to any portion of their sons' time being devoted to that, the direct practical use of which they do not see. My school may be divided into three classes; those who are preparing for one or other of the public schools; those who are preparing for special examinations at Woolwich, and those who will complete their education with me. The first two classes cannot afford to lose any time upon any subject that will not tell directly upon the examinations to which they are respectively looking forward, otherwise the result might be the loss of a scholarship in the one case, and in the other the loss of a place altogether. And how utterly void of all chance Science is, in the former case at least, you can well judge. So that until our Public Schools set us the example, it is very little scientific teaching that we can give to this class of pupils at all events. While with regard to the last class, all that parents wish is that their sons should receive a classical and general education; but any meddling with Science I can assure you some of them look upon as simply an amusement of the master's, obtained at the expense of their sons' time. Nevertheless, as I have already said, I have made Scientific Teaching a regular part of the school course for a short time every week, and am only prevented from extending it much further by the causes named above. The subjects we have taken up hitherto have been elementary physiology and chemistry. For the former we have used Dr. Mapother's "The Body and its Health," while one or two of the elder pupils have gone on to Huxley's "Elementary Lessons in Physiology." And when it is considered that the average age of our pupils is only about twelve or thirteen years, I think this is as much as could be expected. For chemistry, we have been very much puzzled to find a suitable text-book; for though there is no want of really first-class books, we have not been able to obtain what we wish. Both Wilson's (published by Chambers) and Roscoe's "Elementary Lessons" are too long, and (considering the objections of parents named above) too high in price for school boys. What we want is something about half the size and price of either of these, which might be made the groundwork for lectures. As it is, we have been compelled to depend upon lectures alone, illustrated by experiments, in which the pupils themselves are allowed to have as much share as possible. I should be much obliged to any of your readers who could direct me to any text-book likely to meet the want I have indicated. We are now intending to combine with the subject named above a little Natural Philosophy; and I may add, that we have already had, some time ago, a twelve months' course on electricity, with experiments.

I think, however, that the whole subject of Science Teaching in schools wants treating by some master hand; and if some such man as Prof. Tyndall, for instance, who, in addition to the highest scientific attainments, knows something about the practical difficulties of the matter, would enter into the whole subject in your columns, advising what to teach, how to teach it, and what books to use, he would, I am sure, confer a real benefit upon Science. We have heard enough about the *want* of it; we want now to be told by competent authority how the want may be best supplied. And I am able to say from my own personal knowledge that there are heads of schools quite convinced of the importance of the subject, but utterly ignorant how to set about remedying it. Upon this point I wish to be very emphatic, and indeed it was chiefly for the purpose of urging this that I began this letter, knowing as I do well, both from observation and experience, the practical difficulties of the subject; difficulties which are much, very much, greater than your enthusiastic philosophers have any idea of. I hope, however, that if the subject be taken up at all, it will be by some one practically conversant with it, who can give advice which will be worth taking.

M. A.

Forms of Clouds

CLOUDY formations worthy of being noticed have been observed by me during the week. On the 8th I chanced to take a walk with M. Gustave Flourens, who has since been sentenced to death by court-martial. At five o'clock we witnessed many ribboned clouds parallel to each other, and so long that they appeared to radiate from a common focus. These ribboned clouds terminated abruptly just over our heads, and their extremities were n*oalescent*, so that the appearance was one of a feather with the vanes of the quill emanating from one side. The wind was blowing



perpendicularly to the vanes and parallel to the quill. This accumulation of matter was evidently owing to the purity of the air on the other side of the singular cloud-edge.

I witnessed again these phenomena on the 9th and on the 10th of March, but not so well. On the 9th and 10th I also observed two solar halos well defined. The halo had a peculiarity of its own. The clouds adjoining the edge were tinged most delicately with violet on the south-easterly side. The evening was stormy and rainy, which is consistent with the theory I have advocated that halos are a prognostic of bad weather.

W. DE FONVIELLE

The Limits of Numerical Discrimination

THE solution of the Problem "how many objects can a man count at once?" is not general, but depends especially on the grouping, position, angular distance, similarity and nature of the objects counted, as well as on the experience and health of the person who counts them.

(This is written under the supposition that the word "count" means "tell the number of," not "begin, one, two, three," which of course cannot be done simultaneously.)

As an example of the operations performed in counting, take the card "ten of diamonds." The player passes his eyes up and down it, recognises it to be the ten, discriminating it from the other cards, calls it by its name "ten," and then, if he likes, can count separately the pips on the card.

This is a case in which the number of the card is recognised as its name, and many others could be adduced in which much higher numbers arranged symmetrically could be recognised at a glance without counting.

A person habituated to counting would divide the objects into groups with which he was best acquainted, in a way depending on their position.

To show that running the eye over the object is not necessarily conscious, or the very operation of counting—If anyone on a fine sunny day looks through a latticed window for some time and then shuts his eyes, he will be able to count a great number of panes in the impression on his retina, or wherever it is. (Compare with this operation that of recognising a person after he has passed out of sight.)

Looking at a collection of objects in counting by groups is governed by the same laws as looking at a single complex object, and naming follows after the object has been properly discriminated. I can imagine that a person naturally gifted with a memory for form of a certain kind, could by practice at once recognise the number of a large quantity of coins scattered at random, inasmuch as the number would be sharply discriminated from the one higher and the one lower, just as a shepherd discriminates sheep, which to other eyes are alike, and if he can discriminate 36 from 35 and 37, there is no necessity for him to count 36 to say that 36 are there. That can be done afterwards. There should be no astonishment that anyone should possess this power, for after all what is it in comparison to the marvellous faculty we have of seeing highly complex objects at once, which we can analyse to a certain extent; but in no way resolve into the elements of the synthesis. The discrimination between red and yellow, between one note and the next, seems to demand much finer powers of the memory; but we are not astonished at it.

The explanation of many wonderful mental and manual feats depends on the same marvellous faculty of apprehending and considering as one that which formerly could be only considered as very many. Reading words, playing a musical instrument (whether with or without notes), writing, tying knots, doing needlework, the manufacture of every useful thing, all are acquired through the same faculty of changing several simple movements into one complex movement, which is treated as one, and can be named as one, even before it is analysed. It is only fair to infer that counting by groups is an art which may be learned, and, if worth the while, carried to a high degree of practical excellence.

Your correspondent "J. B." (March 9) illustrates Dugald Stewart's view by the examples of two beans and two eyes; these do not prove anything in regard to mental attention, but only that they were not both opposite the parts of the retina with which the observer could see most comfortably. If they had only a small but perceptible angular distance, and did not dazzle so as to tire the eyes, what he mentions would probably not have occurred. He could remember them both together and then count them as well as if he were actually looking at them.

Eccles, March 14 R. V.

Books Wanted

COULD you kindly inform me where I could obtain the following works mentioned by Sir John Herschel in his "Discourse on Natural Philosophy," viz.—Bracconot, "Annales de Chimie," and "Dr. Prout's Account of the Experiments of Professor Autenrieth, of Tubingen," Phil. Trans. 1827. My efforts to obtain these books have hitherto been in vain; if you could assist me, I should feel much obliged.

Newbridge, March 12 H. J. WATSON

Quinary Music

YOUR correspondent, Beacon Lough, will find a very effective specimen of this division in the concluding Allegro to the glee "The Gipsy," written by Wm. Reeve. W. R. M.

The Earthquake

THE earthquake, which caused considerable alarm throughout the North of England on the night of the 17th, was felt severely here between 11.5 and 11.10 P.M. The sky, which had been overcast during the evening, suddenly cleared up towards 11 P.M., but was again completely covered at 11.15. The barometer was heaving during the night, but no special disturbance is registered on the photographic curve; the corrected reading at 11 P.M. was 29·887, and 29·885 at $11^h 11^m$.

The rise of temperature was rather sudden just before the passage of the earth-wave, attaining its maximum, 43·4° at $11^h 11^m$, the wet bulb being then 42·4°.

For most of the afternoon the wind was W.S.W., and was changing from W.N.W. to S.W. between 11 P.M. and midnight; at the time of the shock it was due W. It was blowing gently at the average rate of some thirteen miles an hour from the previous midday, and at scarcely four per hour after midnight. At 10 P.M. its velocity was nine miles an hour.

The trace on the magnetic declination curve shows that the magnet was moving rather rapidly from W. to N. when the shock occurred, and a slight irregular movement at $11^h 1^m$ may be due to the earthquake. The magnets were very quiet before 10 P.M., and disturbed from 10 until morning.

The shock was felt very generally throughout the neighbouring villages.

The sound is generally described as that of a strong gust of wind, followed by a noise resembling the passage of an express train over a wooden bridge. This was followed by a very distinct rocking of the furniture, beds, and walls; the whole of the houses seemed to shake violently, and the floors to rise; the rooms swayed backwards and forwards several times. The motion was violent enough to awaken persons from their first sleep. Many thought that part of the building had fallen in, or that something heavy had tumbled down in a room over-head. The rushing sound and crash were followed by a rumbling noise. The motion appeared to begin suddenly, to grow stronger for a time, and then to die away. It was more regular and powerful than the shaking from a heavy waggon in the houses of an old street.

The time the whole disturbances lasted is generally estimated at about half a minute; but this, I should be inclined to think, is excessive.

The direction of the motion is supposed by most to have been from E. to W. S. J. PERRY

Stonyhurst College Observatory, March 20

ALL who are acquainted with the North of England are aware that the districts comprising the counties of Northumberland, Durham, and Yorkshire, are physically divided from that occupied by those of Cumberland, Westmoreland, and Lancashire by a ridge or watershed, formed by the Pennine chain, which is a range of hills averaging 1,700 feet in height, composed of Lower Carboniferous strata, through the centre of which runs the Pennine or "Anticlinal Fault," which has the effect of throwing the strata in a downwards direction to the east and to the west, like the slopes of the ridge of a roof of a house.

To the west of this ridge, in Lancashire, are low undulating plains of Coal measures, and Triassic rocks, much faulted and covered with glacial drift, and in Cumberland and Westmoreland the high mountains and deep valleys of the Lake District intervene between it and the sea. These mountains, composed of Silurian rocks, existed as such, long before the anticlinal fault heaved the Pennine chain into existence, and long before the Oolite strata, forming the high Yorkshire Wolds on the eastern side of the watershed were deposited at the bottom of the sea. In the West Riding the moors have been cut, by the long-continued action of running water, into the deep ravines, or vales, which form so characteristic a feature of that district. It is an interesting question to observe how far this general arrangement of country, and the strata of which it is composed and the dislocations which the latter has suffered, appear to affect the direction, localities visited, and the distribution of the lines of greatest intensity, of the earth-wave which visited the northern counties on the night of the 17th inst. The tract over which it was felt, as far as at present known, would be comprised within a circle, with a centre about ten miles due east of Sedbergh, the diameter of which would be a line drawn from Dumfries to Doncaster, the farthest limits to the north-west and to the south-east, respectively, to which the earth-wave extended. The greatest effects appear to have been experienced in a belt, about thirty miles broad, running inside this circle, the inner margin running along the towns of Scarborough, New Malton, York, Leeds, and Bradford, Preston, Longridge, Kendal, Penrith, Carlisle, Newcastle, and Sunderland, and thence probably passing out to sea and curving round to Scarborough. The outer margin, or circle before mentioned, runs by the Humber, Doncaster, Manchester, Salford, Roby, Huyton, Seaforth, Southport, and probably for some distance out to sea, Blackpool, west of Ulverstone and Coniston Lake, Dumfries, by the north of Tyneside, to the sea. If this belt be drawn on a map, it will be seen that that segment of the circle which occurs from Sunderland to Scarborough, falls entirely out to sea, and up to the present time the earthquake is not known to have been felt on that coast between these points. It would therefore appear probable that this earth-wave traversed the country in a circular belt, the entire north-eastern segment and the outer margin of the Lancashire portion being beneath the sea; that the area of greatest intensity was near the inner margin, but especially at Preston, Lancaster, Ulverstone, and Blaydon, near Newcastle; that the area in Yorkshire, within this belt, was not entirely free from the shock, as it was slightly felt in Wensleydale and Swaledale, on the eastern slopes of the Pennine chain.

At Preston, where the earthquake occurred at 11.4 P.M. Greenwich time, the motion I observed to be from south-east to north-west; the oscillation was considerable, and the hollow noise, which commenced and ceased with the vibration, resembled express trains running in underground tunnels. The air was close and oppressive, the wind S.W., the night starless and hazy, and the sky from the N.W. to the N.E. covered by a peculiar glare, resembling an incipient aurora, which lasted until 1.30 A.M.

In several places more than one shock is reported to have occurred: thus at Singleton Brook, Manchester, the first shock occurred at 10.56; the second, lasting two seconds, at 11.5; and the third, lasting four seconds, half a second after. Two shocks near together were also felt at Leeds, the second being the sharpest, which was felt at Armley, Headingley, Woodhouse, New Leeds, Chapeltown, and West Bar. Two shocks also ocurred at Kendal, the first at 6.20 P.M.; the second, which was the most severe, at 11.15, lasting twelve seconds, that experienced by myself at Preston lasting about seventeen. From Grasmere also three shocks are reported, the first being at 6.40, and the second and worst at 11 P.M. At Ambleside, the first shock was also felt at 6.30, the true time probably of the two noted above, the second being at 11.3 P.M. At Coniston, a slight shock was felt at 7.0 P.M. on the 17th, and another at 6.3 A.M. on the 18th.

At Hexham, the chief shock is recorded as taking place at 11.15; Ambleside, 11.3; Ulverston, 11.5; Preston (by myself), 11.5; Bowdon, Manchester, 11.4; Singleton Brook, Manchester, 11.4; Newcastle, 11.30; Leeds, 11.15; Penrith, 11.4; Liverpool, 11.15; Kendal, 11.15; from which it will be seen that localities, comparatively near together, often differ more as to the time of occurrence than some of those far apart, and thus there is, therefore, strong reason to believe that these various observations (from 10.30 P.M. to 11.30 P.M.) represent one shock, occurring practically at the same moment over the whole area about 11.5 P.M.

In the year 1786, on August 11, an earthquake which extended over nearly a similar area to the present, like it, slightly displaced the waters of Windermere and the Lake District was felt; and the same district was also visited by an earthquake on Feb. 22, 1867, which was particularly felt on the north shores of Morecambe Bay. It is curious to observe that the *northern* margin of the area of the earthquake, which was felt over the greater part of central and southern England, in 1863, exactly coincides with the *southern* margin of the present, and that the latter, in its course to the north-west, directly crossed the Pennine chain in two places.

H.M. Geological Survey, C. E. de RANCE
28, Jermyn Street

ON Friday night last, March 17, at 11 P.M., we had a slight shock of an earthquake. I was reading, when suddenly I imagined I heard a carriage and pair drive rapidly up to the house, then rapidly drive on, there being a pause of half a second at least between the two rumbling sounds. After the second sound had continued a second, the house began to shake to such a degree that I rushed out of doors. The only damage done was that all the ceilings on the ground floor show cracks in the plaster. No doubt you will hear more of this from other correspondents. GEO. H. SAVAGE

Nent Head, Alston Moor, Cumberland

Lunar Halos: their Origin and Prognostic Significance

M. W. DE FONVIELLE is, no doubt, right in attaching importance to the study of these phenomena of refraction, depending as they do, upon the polarisation of atmospheric vapour. Rightly interpreted, they afford one of the most certain indications of weather change, especially in regard to rain; but the popular notion of their being precursors of storms is certainly exaggerated. In reply to hee inquiry made by M. de Fonvielle, I may say that the distance between the observers of the singular forms of this phenomenon, and seen on January 4th (and of which a sketch, furnished by me, was inverted by the printer) was about two statute miles. I have ascertained that the two arcs in my own sketch corresponded with the largest and the smallest circles in the drawing of your other correspondent. I saw nothing of the intermediate intersecting arc, almost vertical* in his drawing.

M. de Fonvielle does not, however, remark on the fact that the great circle of 90° had the moon in its *circumference*. Allow me also to add that in my own sketch the apparent diameter of the moon and of the imperfect paraselene are exaggerated; the object of the drawing being to show the relative magnitude and position of the two circles. The innermost circle in both drawn ings was about 45° to 50°—in fact an ordinary lunar halo. All my observations (for many years) have pointed to the inference, which I may call a law, "*That halos indicate a change of temperature*, and are indicative of transition from dry to wet as well as from wet to dry." I shall be happy to forward M. de Fonvielle further information if desired.

Aigburth, Liverpool, March 20 SAMUEL BARBER

Science in Schools

IN the last number of your paper a correspondent, "W.," asks for information respecting "any school adapted for young boys whose parents wish to give them an education embracing the physical sciences and modern languages, on some such plan as that of the Realschule of Germany." Will you permit me to state that the International College at Spring Grove was established with precisely this object, and to a prospectus of this college, which I send you, I would direct the attention of your correspondent. The scheme of science instruction for this college was drawn up by Professors Huxley, Tyndall, and Williamson, and for upwards of four years past has been carried into operation as closely as circumstances permit.

Isleworth W. F. B.

IN reply to "W." will you allow me to forward you a prospectus of Craufurd College, Maidenhead, in which an education is given embracing the physical sciences and the modern languages. Having many years ago visited the Realschule of Offenbach, and attended the classes of several of the professors in that school, I have no hesitation in expressing my opinion that a comparison of the merits of the two schools would not be unfavourable to the former. ANGLICUS

Morell's Geometry

AS a considerable part of your number of February 23 is devoted to comments on a little publication just issued by me, "The Essentials of Geometry," I must request you in courtesy to insert these lines in order to set right one misconception. "The Reviewer" (p. 323) passes certain criticisms on the definitions and enunciations, as well as demonstrations, of the book, describing the former as having salient incongruities, and the latter as being nonsense. These are strong expressions, but my present purpose is not to expose the fallacy of the remarks in the review, but to point out the fact noticed in the preface, and overlooked by the reviewer, that all the proofs in the work are taken from French and German sources (p. viii.)

I may add that those sources are the most approved in neighbouring countries, and though I have not given my references in every case, I have done so in so many cases that any person of ordinary discrimination might have inferred that every statement and proof advanced had some high authority for warrant. It is to be regretted that the "Reviewer" overlooked this, for in his haste to condemn a method for which he has an antipathy, he has been betrayed into accusing some even of the leading British as well as foreign geometricians as guilty of salient incongruities, and of writing nonsense. Thus the definition of a plane angle, though condemned by "The Reviewer," is almost identical with that of Dr. Thomson in his edition of Euclid (1835), Def. 7, and the Note to it which runs: "A rectilinear angle is the degree of opening or divergence of two straight lines which meet one another." Nor does Euclid's original definition of an angle differ in conception from that given by me, γωνία ἐστὶν ἡ πρὸς ἀλλήλας τῶν γραμμῶν κλίσις; for this word κλίνειν contains the notion of revolution, that is, of more or less. Compare my second definition of an angle.—*Essentials*, No. 68, p. 40.

Again, the enunciation and demonstration of the two fundamental theorems of parallels are qualified as sheer nonsense, and yet the whole passage is textually the same as Amiot's, including the parts printed in italics. Further, the proof of the equality of triangles at p. 44, condemned as a violation of the common rules of logic, is based on the previous pages 42, 43, overlooked by "The Reviewer," and agrees almost word for word with Legendre, and absolutely with M. Bos, Professor of the Lycée St. Louis at Paris, and successor of Amiot. (See his "Memento du Baccalaureat es Lettres," 1866-68, p. 183. Partie Scientifique.)

It would take up too much time and space to go further into the matter in dispute, but I wish it to be clearly understood, without denying the right of "The Reviewer" to attack the book in any way that is fair and reasonable, that it is neither one nor the other to make Mr. Morell the object of all the attacks when he is far too honoured in being treated as the substitute for many of the first geometers of the present age on whom the punishment descends.

Every statement and proof in the work has for its warrant some high authority, and the basis of the work and most parts of it to which no special references are given in foot-notes are taken from a digest published by University examiners and Doctors of Science on the Continent.

Now, Sir, as the present letter does not presume to enter on a discussion of the merits or demerits of the work, but is simply an explanation of an essential point underlying the whole question and overlooked by "The Reviewer," I must, as I have said before, request these remarks to be inserted in NATURE to set right the mistake about the authorship and authority of the book.

If NATURE will have the courtesy to give me a little more space on a future occasion, I hope to show on my own authority that I have good arguments for what has been advanced.

March 15 J. R. MORELL

Work and Force

AS I hope to hear more of Mr. Highton's arguments at the meeting of the Literary and Philosophical Society of Manchester before this is printed, I will content myself now with noticing but two points.

The first is his attempt to defend himself from the charge of confusing Work and Force; there are other passages in his writings which lead to this somewhat serious conclusion; but the vagueness of the expression "the total of the force used" would suffice to make anyone suspect some such confusion. I presume that a "total of force" is still force, and can therefore be no more equivalent to work than to a time or a space.

The other point is the sentence "this only shows that one of the laws of thermo-dynamics is inconsistent with the doctrine of the mechanical equivalence of heat." If Mr. Highton knew that the first law of thermo-dynamics simply asserted this equivalence he would surely have expressed the proposition differently. As it stands in form it is very much the same as if he had said that one of Newton's laws of motion was inconsistent with the principle that a particle acted on by no forces will move uniformly in a straight line.

If he had known what the laws were, he would hardly have said that they were inconsistent with the very principle which the first asserts, and which the second, as usually stated, involves.

Of course, these lines are not meant as an answer to Mr. Highton's letter, but merely to show that he really does not quite understand the theory he criticises.

March 18 J. HOPKINSON

INVINCIBLE ignorance is said to be excusable. This must be my plea, when I say that I have read over again Sir W. Thomson's paper in the "Philosophical Magazine" of Feb. 1854, and that I cannot see but that it leads to perpetual motion more than anything I have ever written.

H. HIGHTON

* See NATURE, Jan. 26.

AMERICAN NOTES

We are again indebted to the early sheets of *Harper's Weekly* for the following :—At a late meeting of the Boston Society of Natural History a communication was presented by Count Pourtales in reference to the character of the sea bottom off the coast of the United States, south of Cape Hatteras, and based upon the researches of the Coast Survey. According to his statement, the principal constituent of the coast is silicious sand from the coast-line to about the line of one hundred fathoms—a limit which coincides nearly with the inner edge of the Gulf Stream throughout the greater part of its course. Outside of this line is a whitish calcareous mud, containing globigerina, and extending probably over the greater part of the ocean. South of the Vineyard Islands, and to the eastern end of Long Island, the silicious sand is replaced by a kind of bluish mud, known as the Block Island soundings. A similar mud is found off Sandy Hook in a range of depressions known as mud holes, which form a leading mark by which to find the port of New York in thick weather. A few rocky patches are found east of the neighbourhood of New York, and a rocky bottom occurs, sparingly, near Cape Fear ; but otherwise the sand is pretty uniform, varying only in the size of its grain. On the inner edge of the Gulf Stream there is a deposit of greensand composed of the cast-off foraminifera.—According to late advices from Florida, Mr. N. H. Bishop, whose visit to that State in the interest of natural history we have already referred to, has started off in his yacht on a cruise down the coast for the purpose of making collections of Florida birds, &c. He hopes to penetrate into the Everglades and prosecute some inquiries in regard to certain species of birds said to occur there, and no where else in Florida.—We regret to have to record the death, at St. Paul, Minnesota, on the 13th of December last, of Prof. William Chauvenet, formerly Chancellor of Washington University, St. Louis. This gentleman has long been known in American scientific circles for his attainment as a mathematician and astronomer ; and the various works published by him have occupied a high position as text-books and manuals of instruction. For a time connected with the Naval Academy at Annapolis, he was subsequently elected Professor of Astronomy and Mathematics in Washington University, St. Louis, afterwards becoming Chancellor, and remaining there until 1869. His death occurred in consequence of exhaustion of the nervous powers at the age of a little over fifty.—We regret to learn that in the course of a disastrous fire at Springfield, Illinois, on the 25th of February, the collection of the Geological Survey of the State of Illinois was in large part either destroyed or greatly injured, especially the fossil plants. This loss is the more severe, as the collection in question contained one of the finest series of Carboniferous fossils in the country, and embraced a large number of types of new species described by Messrs. Worthen and Meek. This should be a warning to all who have charge of valuable natural history collections, to give themselves no rest until their treasures are secured in fire-proof buildings.—We recently called attention to the excessive degree of cold to which meteorological observers on Mount Washington have been subjected during the present winter. Since then still greater inclemency has been recorded, during which the thermometer was fifty degrees below zero, while the wind had a velocity of one hundred miles an hour.—We have already, in a previous number, referred to the examination of a locality in California, by Prof. Marsh's exploring party, where numerous fossil trees had previously been discovered ; and we learn that a detailed report may be looked for in the April number of the *Journal of Science*. The region in question is situated on a high, rocky ridge in Napa County, California, near Calistoga Hot Springs, and about ten miles from the summit of Mount St. Helena. The ridge itself belongs to the Coast Range series, and forms the division between the Napa and Santa Rosa valleys. It is about two thousand feet in height, and is composed of metamorphic rock of the cretaceous period, overlain unconformably by later tertiary strata, consisting of light-coloured, coarse sandstone, and beds of stratified volcanic ashes. A careful examination showed that the trees on the surface of the ground had been weathered out of the volcanic tufa and sandstone, and consequently were of the Tertiary age ; and also that there remained still embedded in the volcanic tufa, &c., an extensive forest of very large trees, stretching over a great area. Some of the trees were of great size, a portion of one having been traced for a length of sixty-three feet, with a diameter of seven feet near its smaller end. Another tree indicated an original diameter of not less than twelve feet. All were prostrate, and had apparently been thrown down by the volcanic current which covered them, Many were much decayed internally and worm-eaten before they were buried. All of the wood was silicified, probably by means of hot alkaline waters containing silica in solution—a frequent result of volcanic action. A careful examination of the wood obtained at this locality showed no essential difference in structure from that of the modern redwoods of California (of the genus *Sequoia*). No other fossils were met with, which rendered it somewhat difficult to fix the precise epoch ; but it is considered probable by the Professor that the trees belonged to the Pliocene period. The origin of the volcanic material which covered the forest could not be ascertained, although it was supposed to have been derived from Mount St. Helena, which is the nearest volcanic peak.

THE SCIENCE AND ART DEPARTMENT

WITH reference to examinations in large towns, the Department had previously issued the following regulation :—" In large towns or populous districts where there are three or more schools, and where numerous examinations are to be held, the Science and Art Department *may at its discretion require* a special local secretary to be appointed to manage the whole of the examination business. The Department will correspond with him alone on all subjects connected with the examination. He will be allowed a fee of ten guineas, and an extra fee of half a guinea for each night on which an examination is held."

The Department has now determined to place the conduct of these examinations as far as possible in the hands of officers appointed by the School Boards with the approval of the Science and Art Department. In such cases the School Board would determine, in concert with an Inspector from the Science and Art Department, the centres at which the examinations were to be held. They would appoint officers, one of them as special local secretary, with such a staff of assistants as would secure the presence of at least two, or if the number of candidates were very large, more officers at each examination. The examination papers would be sent to the officers appointed by the School Boards as they are now to the Local Committees. While these officers would be responsible for the conduct of the examinations, it would be expected that a few members of each of the Local Committees would visit the examinations and satisfy themselves with regard to the pupils of the classes they superintend. The same payment will be made to the special local secretary appointed by the Board as is now made to the special local secretary elected by the Committees ; and they would make a payment to each assistant of 10*s*. for each night he was required to attend.

With regard to the number of Science Schools in which no fees are charged, or in which they are merely nominal, the Department thinks that the schools cannot be considered in a wholesome condition when students, a very large proportion of whom are adults in the receipt of wages, obtain their instruction wholly at the cost of the State and without any pecuniary contribution on their part. Nor is it probable that they will value as they ought what is given gratuitously. The directions in the Science Directory are very plain on the point. They state that "the payment of fees by the students can be looked upon as the only solid and sufficient basis on which a self-supporting system can be established and supported. Though the Department does not consider it necessary at present to lay down any rules making the payment of fees an absolute condition of the grants on account of Science instruction, yet as the payments from the State must be expected to diminish, and as aid on account of those persons who do nothing for themselves cannot be justified, committees of schools and classes and teachers are strongly urged (should it at present not be the practice) at once to impose as high a scale of fees as they consider can be raised not only on middle class students but also on artisans." The Department desires to call the serious attention of the Committees of Schools to this instruction where fees are not imposed. They find that in some places not only is there an entire absence of fees, but that there has even been an unseemly competition on the part of teachers to get students by any means to join their classes with a view of earning the payments on results. They therefore give notice to the Committees of Schools that unless they themselves take steps to remedy the present evils by imposing at least some small fees, which should be paid to the Committee direct, it will be necessary to reduce the amount of the payments on results. They have no wish to reduce the payments on results at present, and they would avoid as long as possible the imposition of new conditions which necessarily complicate the system of aid, and render the rules burdensome and difficult to work under, but the want of proper vigilance on the part of the Committees may render this step necessary.

AUGUSTUS DE MORGAN

THOSE readers of NATURE who are in the habit of examining the obituary column of the *Times*, will have regretted to see, on Monday morning last, the announcement of the death of the eminent mathematician, Augustus De Morgan. He had been seriously ill for the past two years. A disease of the kidneys, complicated with other disorders, had reduced him to a shadow of his former self, and rendered him incapable of any protracted exertion. This was the more trying as his mind retained all its former energy, and the doctors forbade his reading more than an hour or two in the day. He was, however, allowed to see his friends, and often amused and instructed them by the hour together from the stores of his extraordinary memory. During the last few weeks he had become considerably weaker, and on Saturday the 18th, at one o'clock in the afternoon, his spirit was released from the body which for so many months had been only a burden to it.

Augustus De Morgan was the son of a Colonel in the Madras army. He could trace his descent from the mathematician, James Dodson, author of the "Anti-Logarithmic Canon." He was born in the summer of 1806, in Southern India. While yet a school-boy, he showed his taste for mathematics by filling thick notebooks with "infinite series," which he interspersed with grotesque figures and quaint faces. In 1823 he went to Cambridge, where he entered at Trinity College; his rooms were in the south-east corner of the great court, then called "Mutton Hole Corner," which he affirmed was a contraction from Merton Hall Corner.

In the tripos of 1827 he was Fourth Wrangler, but he never proceeded to the degree of M.A., owing to his objection to subscribe to the tests, and it is sad to think that the same conscientious scruples debarred this illustrious man from a Fellowship. On leaving Cambridge he entered at Lincoln's Inn, and would have forsaken Mathematics for the study of the Law, but that in 1828, the London University, now University College, was founded, and he was offered the Professorship of Mathematics there, which he accepted, and remained a firm supporter of the College and its principle of no tests till the year 1866, when the Council, in making an appointment to the chair of Logic and Mental Philosophy, refused, as the Professor believed, one of the candidates on account of his religious opinions. Prof. De Morgan remonstrated, but his remonstrances were disregarded. He then thought it his duty to inform them that he must forsake the College if the College forsook its principles. But the Council turned a deaf ear; and Prof. de Morgan, who had for nearly forty years been the chief honour and ornament of their institution, left them, and, we are informed, never afterwards entered their gates.

To estimate the energy of the Professor we must look at him not only as a teacher of mathematics, but as a mathematician, an actuary, a logician, an historian, a biographer, and a bibliophile. First, then, as a teacher of mathematics perhaps no man has been more successful in training distinguished mathematicians. Amongst the latter we may mention the names of Prof. Clifton, Judge Hargreave, Mr. Routh, and Mr. Todhunter. Prof. Sylvester also attended his lectures, though the relationship of professor and pupil did not in this case last very long. He had a method of interesting his hearers in the subjects on which he lectured, and of making them love mathematics for its own sake, which few other men have ever attained to. He expended a great deal of work upon his classes. The subject-matter of every lecture which he delivered was entered in a note-book and sent into the library of the college for the benefit of his pupils while writing out and expanding their own notes.

As a mathematician, his work was so various that it is difficult for any one man to review it, and it would be out of place to attempt anything of the kind here; but we may allude in passing to his double algebra, which was certainly the forerunner of Quarternions, and contained the geometrical interpretation of the symbol $\sqrt{-1}$. Sir W. R. Hamilton, in the preface to his Lectures on Quaternions, p. 41, says, "But I wish to mention that among the circumstances which assisted to prevent me from losing sight of the general subjects, and from wholly abandoning the attempt to turn to some useful account those early speculations of mine, on triplets and on sets, was probably the publication of Prof. De Morgan's first paper on the 'Foundation of Algebra,' of which he sent me a copy in 1841."

As a writer of mathematical text books, he took the highest rank, his books being more suitable, however, for teachers than for pupils. They were characterised by extreme clearness, exhaustiveness, and suggestiveness. Perhaps those best known are his "Elements of Arithmetic," published 1830; his "Elements of Algebra," published 1835; and his "Differential and Integral Calculus, with elementary illustrations," which is a perfect mine of original thought, and in which some of the most important extensions which the subject has since received, are distinctly indicated, and it was published by the Society for the Diffusion of Useful Knowledge.

As an actuary he occupied the first place, though he was not directly associated with any particular office, but his opinion was sought for on all sides, by actuaries, on questions connected with the theory of probabilities as applied to life contingencies. In 1838 he wrote his "Essay on Probabilities," which still retains a high place among the literature of insurance offices.

As a logician he was well known, and his "Formal Logic," together with the Treatise of Mr. Boole, may be said to have created a new era in logical science. His controversy with Sir William Hamilton will long be remembered.

As an historian and biographer, the English *Encyclopædia* says of him that "he had a great affection for, and an extensive and minute erudition in, all kinds of literary history, biography, and antiquities." He was one of the most extensive contributors to the *Penny Cyclopædia*, many of the articles of scientific biography having been written by him, as well as most of the mathematical and astronomical articles. The lives of Newton and Halley in Knight's "British Worthies," were also from his pen.

As a bibliophile, his "Arithmetical Books from the Invention of Printing to the Present Time, 1847," and his "Budget of Paradoxes" will long remain celebrated. He was the possessor of a very large collection of old mathematical works.

In addition to this the Professor contributed largely to the *Philosophical Magazine*, the *North British Review*, the *Athenæum*, and the Transactions of the Cambridge Philosophical Society, in which he published most of his original investigations. He wrote a "Book of Almanacs," with an Index of Reference, by which the Almanac may be formed for every year up to A.D. 2000, with means of finding the day of the new moon from B.C. 2000 to A.D. 2000. He was also secretary and member of the Council of the Royal Astronomical Society for many years. He and his son, George De Morgan, also a mathematician of great promise, whose untimely death will be remembered, took the most active part in the foundation of the London Mathematical Society, of which he was the first president. Prof. De Morgan will be buried on Thursday, the 23rd, at Kensal Green, but his memory will long be cherished among a large circle of attached and admiring friends.

ARTHUR C. RANYARD

PAPERS ON IRON AND STEEL

IV.—THE BESSEMER PROCESS (*continued*).

THE magnificent shower of sparks which accompanies the turning over of the converter is easily explained. The blast has, of course, to be maintained during this turning over, until the whole of the melted material is clear of the openings through which the blast is forced. As these cover a considerable area at the bottom of the converter, the edge of the liquid passes them successively, and at the moment of thus passing the blast cuts the surface of the melted matter almost horizontally. But what is this melted matter? It is a pool of iron, on the top of which is floating a thick scum of silicate of iron, &c.—the "cinder." I use the term "silicate of iron" only in an approximate sense, as I doubt whether the silica is completely oxidised.

My reasons for doubting it are that the particles which are driven out of the converter by the blast are, to some extent, explosive, they are seen to burst with brilliant coruscations which are partly due to further oxidation; and when the granules which shower upon the floor are examined in the microscope, they present a very curious appearance. They are minute hollow spherules, miniature bomb-shells, varying considerably in diameter from one-tenth of an inch to one-fiftieth and less in diameter. The largest are more or less broken, commonly of a basin shape, shown in Figs 1 and 2.*

The smaller spherules are for the most part perforated. My friend, Mr. Joseph Bragg, who has carefully examined these, and to whom I am indebted for the drawings from which the engravings are copied, says, "I can hardly satisfy myself that any are quite without apertures, though some have no distinct round holes as most have, but in these cases there are minute openings between and under the welded scales or plates which often cover the spherules, giving them a rough surface." Conglomerate groups of these spherules, such as are shown in Figs. 3* and 4, are very common, and some are attached to irregular lumps of cinder, as shown by the right-hand fragment on Fig. 3. A few are pear-shaped (see Fig. 4). On the right of these pear-shaped specimens are shown some of the smaller spherules in which the perforations are less evident. In the smallest, as the agglomerated and attached specimens (Fig. 3), the perforations are very obscure or doubtful.

Sir Samuel Baker, in his "Nile Tributaries of Abyssinia," describes some natural products due to a similar action on a vastly larger scale, viz., the volcanic eruption of a flood of gaseous matter through fused silicates. He says, "Rows of broken hills, all of volcanic origin, broke the flat plain. Conical tumuli of volcanic slag here and there rose to the height of several hundred feet. We entered a dead level plain of orange-coloured sand, surrounded by pyramidal hills; the surface was strewn with objects resembling cannon shot and grape of all sizes, from a 32-pounder downwards; the spot looked like the old battle-fields of some infernal region. . . . I dismounted to examine the Satanic bombs and cannon shot. Many of them were as perfectly round as though cast in a mould, others were egg-shaped, and all were hollow. With some difficulty I broke them, and found them to contain a bright red sand; they were, in fact, volcanic bombs that had been formed by the ejection of molten lava to a great height from active volcanoes; these had become globular in falling, and having cooled before they reached the earth, they retained their forms as hard spherical bodies precisely resembling cannon shot. The exterior was brown, *and appeared rich in iron*. The smaller specimens were the more perfect spheres, as they had cooled quickly, but many of the heavier masses had evidently reached the earth when only half solidified, and had collapsed in falling. The sandy plain was covered with such vestiges of volcanic action, and the infernal bombs lay as imperishable relics of a hailstorm such as may have destroyed Sodom and Gomorrah." To a Lilliputian traveller about an inch and a quarter high the floor of a Bessemer shop would present about the same aspect as this volcanic plain presented to Sir Samuel Baker, and would appear on about the same scale relative to the traveller's own dimensions.

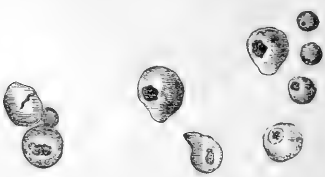


FIG. 4.

It may have been remarked that in the above I have never used the word "slag," which in chemical works is usually applied to the separated silicate of iron, &c., however it may have been separated. I have called it "cinder," in accordance with the nomenclature of the workshop, for in the use of these terms, slag and cinder, the workshop is more learned than the University, even in the matter of etymologies, which occupies so absorbing an amount of University attention.

Whenever the silicate is separated by fusion or the direct action of the fire he calls it "cinder," when it is squeezed out from a bloom or pile by the blows of the hammer he calls it "slag." Now the Scandinavian name of *fire* refuse or dross is *sinner*, the German for the same is *sinter*. The Scandinavian for a blow is *slag*, the German *schlag*. I have observed with much interest the constancy with which the workman adheres to the strictly etymological signification of these words, while learned writers utterly confound them. Of course the workmen are unacquainted with their origin, nor have I ever seen their distinctive etymologies pointed out by anybody else. They afford an interesting illustration of the technical continuity of modern English with its ancient Scandinavian basis. Our metal workers, like our sailors, still speak the strong tongue of the old Norseman. There are scientific as well as etymological reasons for the distinction between cinder and slag, and therefore I adopt the workmen's phraseology.

W. MATTIEU WILLIAMS

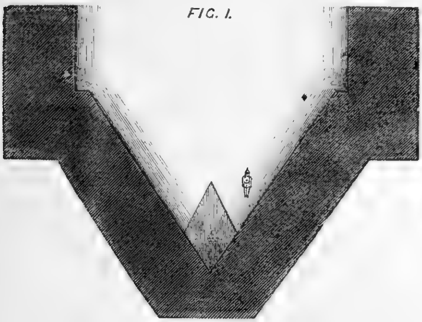
SCIENCE IN GOVERNMENT WORKSHOPS

THERE seems to be a singular antagonism between science and officialism. The Government has undertaken more than one special manufacture, and not without a certain measure of success, but even the best of Government factories are tainted with some

* Figs 1, 2, and 3 will be found in last week's number of NATURE, p. 389

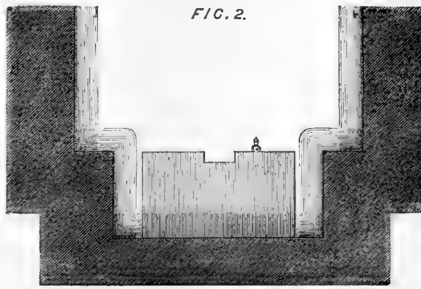
perverse defiance of scientific principles. Why this should be is too large a question for present discussion, but the fact is beyond doubt. Take, for example, one of the most effective seats of national manufacture—the small-arm factory at Enfield, which is under the command of an officer who may fairly be credited with scientific intelligence. You will see there a considerable amount of what may be called imported science. Outside inventions in machinery, in rifle barrels, in locks, in breech-actions, and other branches of the work,

FIG. 1.



have been appreciated, adopted, and improved, and this is so far good. The Snider is a very clever makeshift, and perhaps as good a converted rifle as could have been made out of the old Enfield. The projected Henry-Martini, again, has an excellent breech-action, though not quite the best that might have been selected. Its barrel is on a good and tried pattern, although one that has not very successfully competed with the Metford. In these respects, the design cannot be called unscientific, but it is said that one essential element of the new rifle—the sighting—if not absolutely left to be fixed by tradition and routine, will be in principle little better than the worthless sighting of the old Enfield. If a crack shot were offered the choice between a first-rate barrel with clumsy and unscientific sights and an inferior barrel fitted with perfect sights, he would certainly prefer to enter into a competition with the latter weapon. Errors from defective aim are, as a rule, much larger than those due to imperfections of rifling, and to fit a first-rate weapon with bad sights is to throw away nearly all the skill and money which has been expended upon it. This is just what the people at Enfield are doing now, and all for want of familiarity with one of the simplest maxims of geometrical science. When a mathematician, an astronomer, an engineer, or even a superior artisan, wishes to determine with accuracy the position of a point, he almost invariably does it by setting off its distance from each of a pair of rectangular co-ordinate axes. In very special cases and for very special reasons the advanced geometrician will occasionally employ oblique instead of rectangular axes; but whenever it is practicable, whether he is dealing with linear or angular measure, he uses as a matter of course rectangular axes. In a case where he has to measure independent variations in horizontal and vertical directions, he would think it simply absurd to refer the position of a point to any other than a pair of horizontal and vertical axes of co-ordinates. Thus the astronomer has his co-ordinates of azimuth and altitude, of latitude and longitude, the builder works with his plummet and square, and the most simple-minded carpenter, who wished a nail put in a particular spot on a wall, would order it to be driven in at so many feet from the floor, and so many feet from the side of the room. This elementary scientific method has in fact descended to so low a stratum of intelligent society that most people have assimilated it as if by instinct, and would open their eyes rather widely if they were told that when they practised it they were obeying the dictates of science. And yet, strange as it may seem, this extremely elementary, almost axiomatic, idea of rectangular co-ordinates, has not yet penetrated to the Government factory at Enfield. Consider what the sights of a rifle are for. In the simplest case, when you are aiming at an object the distance of which is known, and when there is no wind, you have nothing to do but to adjust the

FIG. 2.



sights to the right elevation, and align them upon the object. But if your first shot falls low or high, or if you want to hit another object at a different distance, you must do one of two things, either slide your backsight up or down or else take a fuller or finer sight. In other words, you must correct the error in elevation, either by mechanical adjustment or eye-adjustment in the vertical direction. Practically, large and occasional changes are made by mechanical adjustment; small and frequent changes by eye-adjustment. So again, if there is wind to allow for, you must either give the sights an apparatus for lateral adjustment (which, of course, would be quite inadmissible in a military arm), or, you must make the necessary allowances by eye-adjustment in the horizontal direction. The occasions which require vertical and horizontal corrections are quite independent of each other, the one class being functions mainly of distance, and the other of lateral wind. This is, therefore, precisely the case where the position of the sight should be referred to vertical and horizontal lines.

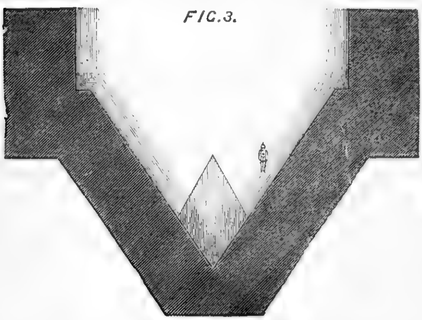
Instead of doing this, our Government manufacturers give you a backsight, bounded by two oblique lines at a certain inclination to the vertical, and they provide you with a foresight, bounded by two other oblique lines at a different inclination to the vertical. When they indulge in a great effort of imagination they sometimes dream of getting rid of the oblique lines on the backsight, still leaving the foresight as bad as ever. Anything more perversely unscientific can scarcely be imagined, though we daresay it will be stoutly defended on the plea that it is the same venerable system which contributed to the non-efficiency of Brown Bess.

To any mechanician, however humble, it must be quite clear that both backsight and foresight ought to be bounded by horizontal and vertical lines. And here we might close the subject but for the stupendous power developed by the military mind, of pooh-poohing suggestions which have only science and reason to recommend them. "Extremely ingenious and scientific, no doubt," our soldier critic may say, "but shows a woeful ignorance of the practical conditions of the problem. You see our recruits are not philosophers, but rough fellows, and we must give them something easy to understand and handle, and capable of bearing rough usage. Experience has shown that there is nothing like the old V backsight and knife-edge foresight, with which the British soldier can go anywhere and do anything, &c. &c. You scientific people always forget to look at the practical side of things."

Now that is just what scientific men don't forget. No man can be really practical unless he is also in his measure scientific. But in this matter of sights it may be worth while to follow the advice of our imaginary soldier, and look more minutely at the practical side of the question. What is the test of a good sight? Obviously the best sight is that which enables the rifleman most easily to judge whether two successive aims are alike, or if they differ, to say in what direction and to what extent they do so. For this reason the soldier is taught to discriminate between fine sights, full sights, and half sights, according to the quantity of foresight which he allows to be visible above the bottom of the V. What he sees is an irregular lozenge, and the accuracy of his shooting, so far as elevation is concerned, depends upon his judging with perfect exactness the length of the vertical diagonal of this lozenge. Again, if wind has to be allowed for, he must fix in his mind the apparent distance at which the tip of the foresight should be seen on the right or left of the object. The difficulty of these eye-adjustments is enormously increased by giving him nothing but inclined datum lines from which to estimate. The language in which it is customary at Hythe to inculcate the method of making allowance for wind, curiously illustrates the absurdity of the received sight-pattern. The recruit is told that he must "aim at nothing to hit something," a phrase really very happy as a description of the difficulty of estimating at the same time elevation and lateral allowance with a Government rifle. The most practised shots find it by no means easy to vary their horizontal allowance for wind without in some degree altering their elevation, and all this difficulty is quite gratuitous.

The true test of the value of a system of sighting is of course to be applied rifle in hand, but our pictures will show tolerably well what the result of such a test would be. Figure 1 is what a man sees when he takes an aim with the present military sights. It is meant for a half-sight, the lozenge in the middle being the portion of foresight visible, and the shading being as near a representation as we can give of the haze which always more or less blurs the outline of the backsight. We have supposed a little wind, and the object is therefore seen on one side of the sight, and is as nearly level with the tip of it as it can be brought without the guidance of any horizontal line. Now suppose the rifleman finds that sight correct, and wishes to shoot down a second enemy at the same range and under the same conditions. He will try to take just the same sort of aim again, and Fig. 3 is a pretty good approach to it. Probably the reader will have to look backwards and forwards rather carefully before he can judge whether there is any, and how much, discrepancy between Figs. 1 and 3, and if (as would be the case in actual practice) Fig. 1 had gone out of existence say only a few minutes before Fig. 3 was looked at, we doubt very much whether the error would be large enough to be discerned at all, and we are sure that its amount would not be correctly estimated.

FIG. 3.

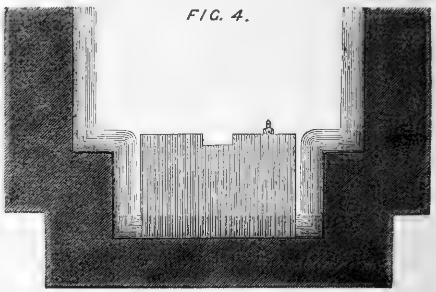


Now, take the case of rectangular sights such as are drawn in Fig. 2. In this, as in Fig. 1, the elevation is supposed to be normal—that is, with the horizontal top of the foresight level with the top of the backsight below the haze. The allowance for wind is exactly the same as in Fig. 1, and its amount may be fixed in the memory by noting that the object is about twice as far from the outer edge of the foresight as it is from the little rectangular notch which marks the middle of it. Having looked at this, it would be quite possible to go away for a day, and then return and look at Fig. 4, and see at once that this latter differs from the former by being a considerably higher sight with a much larger allowance for wind. No error anything like as gross as this could be made even by the poorest shot in two successive aims. And yet the real differences in elevation and horizontal allowance between Figs. 2 and 4 are not larger than those between Figs. 1 and 3, which cannot be detected or remembered without the greatest difficulty. And this is the result simply of substituting rectangular for oblique sights.

"All very pretty," says our soldier, again, "but how are you to get such a sight as you have drawn, on a rifle meant to carry a bayonet and to be used in war?"

We are fortunately able to answer this question. Figs. 2 and 4 are taken from the actual sights of a rifle prepared as follows—A London armoury rifle of Government pattern was taken; the knife-edge of the foresight was filed clean off, leaving the block, and then a small rectangular groove was filed longitudinally in the middle of the block, thus leaving the foresight less liable to injury than before.

FIG. 4.



Then the sliding-bar was turned upside down, and a square notch filed instead of the triangular V.

The rifle so altered was rather fitter for rough work than before, and it was possible to aim with it and to make exact allowance for wind into the bargain. The use of it, too, was incomparably easier for a recruit to learn. We may add that the result of actual shooting with it has been quite conclusive in its favour. And yet the beautiful and expensive Henry-Martini is now being turned out with sights which neutralise one half of the accuracy of the weapon by making accuracy of aim impossible.

It will cost at least 1,000,000*l.* to arm our troops with Henry-Martinis in lieu of Sniders, and on a moderate computation one-third of the gain in accuracy (which may be represented by one-third of the cost) is utterly thrown away by the defective sighting.

If these things were not ascertained facts, it would be hard to believe them possible. Is it even yet too late to stop the mischief? G. W. H.

NOTES

Mr. George Biddell Airy, Astronomer Royal, has been selected by the Council of the Royal Society as a fit and proper person to be nominated as President of that Society on the occurrence of a vacancy, and Mr. Airy has declared his willingness to accept the proffered honour. As General Sir E. Sabine, the present president, has intimated his intention of resigning office at the next annual meeting, the election, which rests with the fellows, will come on at that time. We may congratulate the Society and English science generally on the wise choice which the Council have made. In scientific distinction, administrative ability, and honesty of purpose, the president-elect will prove no unworthy successor of the distinguished man of science who has now for so many years filled the office.

The Royal Irish Academy has approved of the following allocations from the fund for promoting scientific researches :— G. J. Stoney, F.R.S., 50*l.*, "For Researches on the interrupted Spectra of Gases;" Prof. R. S. Ball, 6*l.* (additional), "For Experiments on Vortex Rings;" Prof. Henry Hennessy, F.R.S., 20*l.* (additional), "For Experiments on the friction of Fluids in contact with Solids;" Prof. Thiselton Dyer, 29*l.*, "For Researches on Vegetable Physiology;" Prof. Traquair, M.D., 25*l.*, "For Researches on the Crania of Osseous Fishes."

It is stated that the appointment of Professor of Chemistry and Experimental Physics at the Indian Engineering College will be filled up by the transfer of Mr. Herbert M'Leod from the College of Chemistry. We consider this arrangement one which reflects great credit on those who are responsible for it. Mr. M'Leod has long been known not only as an accomplished chemist, but as one who has the rare gift of imparting his knowledge to others, and he has filled the position he held at the College of Chemistry for many years.

We understand that the names of Dr. Cunningham and Mr. E. Ray Lankester have been selected from the candidates for the vacant Professorship of Natural History in the Queen's College, Belfast, and that it is probable that His Excellency the Lord-Lieutenant will appoint the first named gentleman as successor to Prof. Wyville Thomson.

We are glad to learn that the "Zoological Research Association," concerning which we some weeks ago inserted a note, is now fully established.

We regret to have to record the death on the 7th inst., at the age of sixty-eight, of Mr. Henry Denny, the curator of the Leeds Philosophical and Literary Society, an office he had held since 1825. It is to Mr. Denny's untiring zeal and assiduity that the Leeds Museum owes its high position among provincial institutions of a similar character. Unwearied energy, a great knowledge of science, and unfailing courtesy, were combined in him in a manner which will render it very difficult for the society to supply his place. In addition to the title which he held as Associate of the Linnean Society, Mr. Denny was a corresponding member of the Academy of Natural Sciences of Philadelphia and of the Syro-Egyptian Society of London; honorary member of the Philosophical Society of Dickinson College, Carlisle, Pennsylvania; of the Yorkshire Philosophical Society; the Blackmore Museum, Salisbury; and of the Norfolk and Norwich Museum.

There are few more zealous cultivators of Astronomy than an Indian gentleman, Mr. Nursing Row, a friend of the late Admiral Manners, who has built an observatory at his own expense at Vezagapatam. Although he has recently suffered a heavy loss of property from a cyclone sweeping over his estate, Mr. Nursing Row sent the munificent donations of 100*l.* to the Mansion House Fund for the relief of the distress in Paris, and 100*l.* to the fund for supplying seed and other aid to the French peasantry. He is also a most generous benefactor to the poor in his own neighbourhood.

We learn from Paris that the report which reached the Academy of the death of M. Becquerel, the electrician, and which we copied last week, is incorrect. It was his son, M. Dumeril Becquerel, who died during the investment of Paris.

Dr. Page, of Edinburgh, has commenced a course of thirteen lectures on Geology, descriptive and industrial, in the Mechanics' Institution, Glasgow. The lectures are largely attended by ladies and gentlemen. The study of the science in this large commercial city has received new impetus from the attractive and eloquent manner in which the lecturer presents it. Few, indeed, have the gift which Dr. Page possesses of making scientific study popular. The directors of the Institution are indebted to Dr. Page for enabling them to offer such valuable instruction at so small a charge.

The Council of the Pharmaceutical Society offers a silver medal for the best herbarium collected in any part of the United Kingdom between May 1, 1871, and June 1, 1872. The collections are to consist of flowering plants and ferns, arranged according to the natural system of De Candolle, or any other natural method in common use. No candidate will be allowed to compete unless he be an associate, registered apprentice, or a student of the Society, or if his age exceeds twenty-one years.

We have great pleasure in calling attention to the letters which will be found in our columns of correspondence respecting the International College at Isleworth, and the Crawfurd College at Maidenhead, where instruction in science appears to be given with highly creditable results.

At the last meeting of the American Academy, a new form of solar eye-piece was exhibited by Prof. Pickering. A cube is made by cementing together two right-angled prisms of glass, which is substituted for the reflector in a diagonal eye-piece. By using a cementing liquid whose index of refraction is very nearly the same as that of the glass, almost all the light and heat pass directly through the cube, enfeebling the image so that it can be borne by the eye with impunity. We can thus cut off as much of the light as we please, and yet avoid all danger of cracking the glass by the heat, as frequently happens when a coloured glass is used to absorb it. Since the relative index of refraction of the inclined surface is very nearly unity, the angle of total polarisation is 45°, or the actual angle of incidence. Accordingly, the image will be perfectly polarised, and may be varied in intensity at will by a Nicol's prism. If we make the angle of incidence equal to 45° in Fresnel's formula, it takes the simple form that the reflected light $= \frac{\sin^2 v}{\cos^4 v}$ in which v is the deviation of the ray in passing from one medium to the other. In the present case if $n = 1\cdot01$, we find that the reflected beam equals ·00005, or only one twenty-thousandth part of the intensity of the incident ray, if $n = 1\cdot001$, the light is diminished to one two-millionth. On trying the experiment, it was found that the image formed was coloured, the tint changing with the angle of incidence. This curious effect is probably due to the fact that the dispersion of the balsam used for cementing the prisms is greater than that of the glass, and hence the relative index and quantity of light reflected differ for different colours. Apart from its practical application, this instrument possesses a scientific interest as furnishing a means of making large plane surfaces whose index is nearly unity, and thus enabling us to verify laws for whose proof we have heretofore been dependent on observations with gases only.

A slight shock of earthquake was felt on Friday night in the North of England. In and near Manchester the shock was felt soon after eleven o'clock. At Singleton Brook, near Manchester, the first shock was felt at precisely six minutes to eleven. A resident says that the windows of his house were violently shaken, as though a heavy vehicle was passing along the road. About five minutes past eleven the noise was again heard, accompanied, as before, by a tremulous motion. This time the effect was much more marked and continuous. At first the impression produced was merely that of trembling, which lasted for perhaps two seconds. This was succeeded by a slight pause of about half a second, and then the beds were distinctly felt to roll from side to side, exactly like the heaving of a ship at anchor, and with the same sharp and sudden check to the motion. The time occupied by the second shock was about four seconds. Immediately before the first shock a heaviness in the atmosphere had been noticed, as if there were a sudden change in the temperature. A similar effect was produced, according to concurrent testimony, in the neighbourhood of Bowdon. A decided shock was experienced at Leeds, and from accounts received from York, Wakefield, Doncaster, and other places, it seems to have been pretty generally felt over the southern part of Yorkshire. The accounts obtained from a variety of sources in Leeds show that it was felt in nearly every part of the borough. The statements vary slightly as to the exact time of the occurrence, but it must have taken place from eleven to a quarter-past. There were two motions, the first being very slight—so slight that no notice would probably have been taken, but for a more decided one which followed, and the result of which was that windows were violently shaken in their frames, and in some houses articles of crockery displaced. At Ulverston and Lancaster the shock was felt. Furniture in houses was thrown over, and people shaken and considerably alarmed. Two distinct shocks were experienced in the neighbourhood of Kendal; the first at about 6.20, the second at about 11.15. The first was not violent, and it does not appear to have been generally noticed, but the second was everywhere felt, and created great alarm. It lasted about ten or twelve seconds, and was felt at a distance of sixteen miles from Kendal, on the borders of Yorkshire. It appears to have taken a south-westerly direction. Several witnesses state that at the time of the occurrence they observed an unusual swell in the waters of Windermere lake. During the evening the atmosphere was very calm and foggy, like that preceding a thunderstorm. At Preston the shock was very keenly felt, and it created very much confusion and alarm. In our Correspondence columns will be found several other letters descriptive of the unusual phenomenon.

M. Decaisne, director of the *Jardin des Plantes* at Paris, writing to the *Gardener's Chronicle*, thanks the English horticulturists for their offers of assistance, and asks especially for contributions of Pandanaceæ, Nepenthes, Cyclantheæ, Orchids, and Ferns. "But," he asks, "who will restore to us the Malpighiaceæ which our illustrious predecessor, Adrien de Jussieu, got together with so much pains? Who can give us back the old plants which were deposited here by such men as Aublet, Commerson, or Du Petit Thouars? For many years our stoves must bear the traces of these cruel losses. The effect," he adds, "of the shells on the monocotyledonous plants was very singular, and different in different cases. Thus the Pandanaceæ, Cyclantheæ, and Dracænas had their leaves and young stems completely cut off by the explosions of the shells, while the Bromeliaceæ were uninjured alike by the concussion and by the cold, which destroyed contiguous plants of other families."

We learn from New Zealand that a fine display of Aurora was seen in that colony on the 24th and 25th of October last. It is not a little remarkable that while on the 24th Lyttleton was almost totally burnt down and the colonial papers attributed the blood-red appearance of the sky to the reflection of the fire, many persons in this country actually supposed the appearance of our display to arise from the burning of Paris.

One of the smartest shocks of earthquake known for some time in New Zealand was felt at Wellington at a few minutes past twelve on the night of the 1st of January last.

The Marlborough College Natural History Society has issued its report for the half-year ending Christmas 1870, showing that it continues to prosper and to do good work. The most interesting papers printed at length are one by Mr. F. E. Hulme, "On Mosaic, Ancient, Mediæval, and Modern," containing a history of the art, with a very good illustration; and a prize essay by Mr. J. B. Fuller, "On the Identification of Birds' Eggs;" in which an empirical mode of classification and recognition is given, which will be useful to collectors. As an appendix is printed the commencement of a very careful second edition of a "Flora of Marlborough," by the Rev. T. A. Preston, which is carried on as far as the completion of Thalamifloræ.

The Winchester and Hampshire Scientific and Literary Society has issued its first annual report, a promise, we hope, of good things to come. Although the first meeting was only held in November 1869, under the presidentship of the Rev. C. A. Johns, the society now numbers over a hundred members, and seems to have set itself to do useful work in local and general natural history and physical science. Thirteen papers were read before the society during its first session; and a list of plants collected during the year in the immediate neighbourhood of Winchester is promised with the next report. We would remind those who have to compile this list that grasses are flowering plants, although a sentence in the report before us would seem to imply the contrary. The rapid spread of these local natural history societies is a very healthy sign of the increase of the study of science in the country.

The late numbers of the *Journal of the Scottish Meteorological Society*, of which two, published together, have just appeared, contain, as usual, valuable contributions from Dr. Buchan. In No. 27 he gives his second notice on the Rainfall of Scotland, treating of the central districts from the Firths of Forth and Clyde to the Grampians. The former notice referred to the southern counties. The paper shows that the precipitation in the upper valleys of the Forth and Tay is about 90 inches, or 20 inches more than at the wettest stations in the South. The maximum, 91·90 inches, was observed at Glengyle. It also appears that the amount does not depend on the level of the gauge nearly as much as on local conditions. At Leng, at the height of 325 feet, the amount is 66·37 inches, whereas on Ben Ledi, at the height of 1,800 feet, it is only 58·43 inches. The last number contains a most important paper on the Mean Temperature of these islands, based on the Registrar General's Reports, and on observations from a few foreign stations. The means are taken from the maximum and minimum readings, and in some cases are for thirteen years, in others for less; but all have been reduced to the probable thirteen-year means. Daily range has been disregarded. The paper is illustrated by twelve monthly and a general chart. The results have been carefully discussed by Mr. Buchan, and, whenever possible, with reference to sea temperature. The results for Ireland are of less value than those for Great Britain, owing to the paucity of observations. The paper is specially to be welcomed, as Dove's Tables give but little information for the United Kingdom. The numbers contain some other short papers and the usual tables.

With reference to the flowering of the hazel, the *Gardener's Chronicle* calls attention to the singular fact that male catkins often appear in January, which have completely withered away before the female flowers and a second crop of male catkins appears some weeks later, and pertinently asks, what can be the object of this first crop of catkins?

REPORT ON DEEP-SEA RESEARCHES

Carried on during the months of July, August, and September, 1870, in H.M. Surveying Ship "Porcupine." *

BY W. B. CARPENTER, M.D., F.R.S., AND J. GWYN JEFFREYS, F.R.S.

(*Continued from p.* 334.)

DIRECTING our course again towards the Algerine coast, we kept nearly parallel to it during the greater part of the next day, occasionally sweeping the bottom with the "tangles," which gave us abundance of Polyzoa, Echinoderms, &c., of well-known types, without any specimens of novel or peculiar interest. We reached Algiers on the afternoon of the 26th; and as it was necessary to take in coal, we remained in harbour until the 29th, when we resumed our easterly course, still keeping near the coast. The weather now began to be oppressively hot; the surface-temperature of the sea rising to 76° or 78°, and that of the air being often several degrees higher. Wishing to see what would be the point at which the effect of this extreme superheating would cease to manifest itself, we took a set of serial soundings at Station 53, with the following result, which we incline to consider typical of the condition of the proper surface-water of the Mediterranean in the summer season:—

	° Fahr.
Surface	77
5 Fathoms	76
10 ,,	71
20 ,,	61.5
30 ,,	60
40 ,,	57·3
50 ,,	56·7
100 ,,	55·5

Thus the amount of heat lost in the first 20 fathoms is no less than 15°·5; and as much as 9°·5 of this loss shows itself between 10 and 20 fathoms.

Again proceeding into deep water, we perseveringly explored the bottom with the dredge; and from a bottom of 1,508 fathoms we brought up some hundredweights of the same barren mud as had previously given so much trouble to so little profit. The sieve and the washing-tub again returned for answer "barren all." Disappointing as this negative result was to us as zoologists, there are aspects under which it may be viewed that may give it no small value to geologists. On these, however, we can more fittingly enlarge hereafter. Once more, shifting our ground a few miles, we put down our dredge in 1,456 fathoms, and brought it up loaded with a similar profitless freight.

We now determined to keep closer to the shore, and worked for several days along the African coast, for the most part using the "tangles," the ground being too rocky for the dredge. Here we came upon a small fleet of coral fishers, and were not a little interested in finding that they employed "tangles" similar to our own as their most effective method of collecting. We swept the shore with these very assiduously, usually between 50 and 100 fathoms; and although we obtained Polyzoa, Echinoderms, and corals in considerable abundance, there were not many of special interest. We may note, however, that several of the Polyzoa which occurred in the region in which the red coral is found had, when fresh, a red colour nearly as brilliant as that by which it is characterised; but this colour, in the Polyzoa, was quite evanescent.

The extreme heat of the weather having produced an exhausting effect upon our crew, especially on the engineers and stokers, Capt. Calver considered it desirable to give them rest; and we accordingly made for the Bay of Tunis, which we reached at mid-day on Saturday, Sept. 3rd. The town itself is situated at the head of a shallow lagoon, or salt-lake, that communicates with the sea by a narrow channel, and at this entrance there is a small sea-port named the Goletta, having a basin for vessels of moderate size. The lake, although about six miles long, has only from six to seven feet of water at its deepest part; and when the water is unusually low, a small steamer, which plies between the Goletta and Tunis, is not always able to run, as happened at the time of our visit. Owing to the great evaporation, and the absence of any stream of fresh water, the water of this lake is usually very salt; but when heavy rains fall the level is considerably raised, and the saltness is diminished. Thus the condition of this lake in regard to that of the sea outside is sometimes that of the Mediterranean in regard to that of the Atlantic, and sometimes that of the Baltic towards the German Ocean; and we would suggest whether it might not be possible, through our Consulate (which has an office at the Goletta), to have a regular series of observations made upon the relative densities of the water of the lake and that of the sea, and upon the direction of the upper and under current in the channel of communication between them, that might furnish valuable data for the complete elucidation of the subject of currents occasioned by excess of evaporation. We availed ourselves of this short rest to visit the town of Tunis, which, for the most part, retains its genuine Moorish character; and the ruins of Carthage, a few miles off, the most remarkable part of which consists of a series of immense reservoirs for water, supplied by an aqueduct that brought it from a range of mountains at no great distance, from which also the modern town of Tunis is supplied.

This part of our work having brought us to the neighbourhood of the Island of Pantellaria, we landed on it with the view of visiting, if possible, a cavern which had the reputation of being "of icy coldness." As we found, however, that a whole day's delay would be involved, we gave up the idea; and we afterwards obtained elsewhere the information we desired. The continuance of the very hot weather having brought a large part of our crew to a state of such exhaustion as to render a continuation of our operations undesirable, Captain Calver considered it expedient to proceed to Malta without further delay; and we anchored in the Harbour of Valetta on the morning of Saturday, September 10. Here we found it necessary to remain for ten days, the illness of our chief engineer, which we at first hoped might be only temporary, proving sufficiently serious to require that a substitute should be found for him. Our time was passed very pleasantly in visits to the various objects of interest in which the island abounds, and in the enjoyment of the kind hospitality of His Excellency the Governor, Vice-Admiral Key, and other officers. The time was too short for any careful examination of the geology of the island; but one point which struck me as of special interest in relation to the deposit at present forming on the Mediterranean bottom will be specially noticed hereafter.

Quitting Valetta Harbour at midday on September 20, we steered in a N.E. direction towards a point about sixty miles distant, at which a depth of 1,700 fathoms was marked on the chart. This we reached early the next morning (60); and a sounding being taken, 1,743 fathoms of line ran out. As this was the greatest depth we had anywhere met with in the Mediterranean, and as the basin in which the sounding was taken is cut off by the shallows between Sicily and Tunis from all but superficial communication with the western basin, we watched the heaving-in of the sounding apparatus and its accompaniments with no little interest. The thermometers recorded a temperature of 56°, which was one degree *higher* than that which we had met with in our two deepest soundings (1,456 and 1,508 fathoms) in the western basin. The sample of the bottom brought up in the tube of the sounding apparatus indicated the prevalence of a yellowish clayey deposit so similar to that which had elsewhere proved so disappointing, that we could not feel justified in pressing Capt. Calver for the sacrifice of nearly a whole day, which would have been required for a single cast of the dredge at this depth. The specimen of bottom-water brought up by our water-bottle surprised us by its very small excess of density above the surface-water; the specific gravity of the former being only 1·0283, whilst that of the latter was 1·0281; and the proportion of chlorine per 1,000 being 21·08 in the former, whilst that of the latter was 20·77. The surface-water being here *more* dense than the average, the bottom-water was *less* dense; a result which a good deal surprised us at the time, but which subsequent comparison with the densities of specimens taken from the greatest depths we had sounded in the western basin showed to be by no means exceptional. And when we came to reason out the mode in which surface-evaporation may be presumed to operate in augmenting the density of the water beneath, we found it to be quite in accordance with *a priori* probability, that the *deepest* water should show the *least* excess of density above the water at its surface.

Having thus satisfied ourselves, so far as we could do by a single set of observations, that the physical conditions which we had found to prevail in the western basin of the Mediterranean present themselves also in the eastern, we steered for the coast of Sicily; and in a few hours came in sight of Syracuse, with the lofty mass of Etna as a magnificent background in the remote distance. The clouds which lay upon its summit during the earlier part of the day gradually

* Extracted from the Proceedings of the Royal Society.

dispersed as we approached it, so that we could distinctly trace the outline of its cone, save where this was obscured by a constantly shifting semi-transparent cloud. Whether this was a light smoke given off from the cone, or a film of vapour condensed by the contact of a current of warm moist air with the colder surface of the mountain-summit, we were unable to distinguish, though we watched it with great interest during the whole afternoon. We steamed quietly along the Sicilian coast during the night, so that sunrise the next morning found us in the narrowest part of the Strait of Messina, between Messina and Reggio; and we shall not easily forget the beauty of the spectacle we then beheld on either shore. Passing through the once-dreaded Charybdis, the dangers of which are rather poetical than real, and leaving on our right the picturesque castle-crowned rock of Scylla, we passed out of the "Faro," which narrows at its northernmost extremity to about three and half miles, into the open sea to the north of Sicily, studded by the Lipari Isles; and steered direct for Stromboli, stopping at 10 A.M. to take a sounding (station 61). This gave us a depth of 392 fathoms, and a bottom temperature of 55°·7, which afforded no indication of unusual elevation. Here again we found the density of the bottom-water scarcely in excess of that of the surface-water; and it was even lower than the surface-water in another sounding taken somewhat further on, (station 62), and at a depth of 730 fathoms, which gave a bottom temperature of 55°·3.

	Sp. Gr.	Chlorine.
Surface	1·0281	21·32
Bottom, 392 fathoms . . .	1·0282	21.36
Bottom, 730 fathoms . . .	1·0280	21·22

This result, again, surprised us much at the time; but we are now inclined to attribute it to the decrease of surface-evaporation, consequent upon the marked decrease in the heating-power of the sun, which showed itself in the change of the relative temperatures of the sea and air. For whilst for some days before we put into Malta, the surface-temperature of the sea had ranged between 76° and 78°, and the temperature of the air had been usually about 1° *higher*, we now found that while the surface-temperature of the sea ranged between 73°·6 and 76°·6, the temperature of the air was between 2° and 4° *lower*. This difference continued to show itself nearly all the way to Gibraltar; the daily averages of the surface-temperature of the sea ranging between 73°·1 and 75°·6, whilst those of the temperature of the air ranged between 68°·5 and 72°·0. We now approached the rugged cone of Stromboli, from the summit of which there was constantly issuing—as has been the case since the time when the neighbouring island of Hiera was fabled to be the workshop of Vulcan—a cloud of smoke, indicative of active changes in the molten depths beneath. Of this activity, however, we had found no special indication in the temperature-soundings taken nearest to the island. Whether the *general prevalence* in the neighbourhood of Sicily of a bottom-temperature averaging about a degree above that of the western part of the Mediterranean, is due to subterranean heat, is a question which can only be determined by a larger number of observations than we had the opportunity of making. As we neared Stromboli, we were much struck with the height to which the energetic industry of its inhabitants had carried the vine-cultivation all round the cone, save on two slopes looking N.W. and S.E., over one or other of which there is a continual discharge of volcanic dust and ashes. Although no flames were visible during daylight, we could distinctly perceive occasional flashes as night came on. Our course was now laid straight for Cape de Gat, which we passed on the 27th of September, arriving at Gibraltar on the evening of the 28th. The only scientific observations which we had the opportunity of making during this part of our voyage were confirmatory of those which we had made at the commencement of our Mediterranean cruise as to the lower temperature and inferior density of the surface-water, both which we attribute to the inflow from the Atlantic.

Having taken in at Gibraltar as much coal as we could carry, we left the harbour at 9 A.M. on the 30th September, and proceeded at once towards the scene of our previous observations. We thought it worth while, however, to take a sounding in our way towards this, near the 100-fathom line (station 63), for the sake of ascertaining the temperature and specific gravity of the bottom-water. The depth was found to be 181 fathoms, showing that the slope from the shallow to the deep portion of the channel is here very rapid. The bottom-temperature was 54°·7, that of the surface being 68°; and the specific gravity of the bottom-water was 1·0280, that of the surface being 1·0271. This bottom-water thus agreed closely in both particulars with that of the *deep* mid-channel, as ascertained in our first set of observations, and confirmed by our second.

We then steamed out to a point (station 64) nearly identical with that from which our previous investigations had been carried on; and commenced our work with a temperature-sounding. The surface-temperature (65°·6) proved to be here *less* by 2°·4 than it had been found to be at station 63; and this although it was taken an hour later in the forenoon, when an increase might have been expected. It thus corresponded closely with what had been previously found to be the average temperature of the Strait in mid-channel, both during the first approach at Gibraltar from westwards, and during our own experiments at the commencement of the Mediterranean Cruise; and the continuation of the like observations during the remainder of the day and ensuing night gave the same remarkable result, the *rationale* of which will be considered hereafter. The depth was somewhat less than at the neighbouring station 39, being 460 fathoms instead of 517; but the bottom temperature was a little lower, being 54°·7 instead of 55°·5. The respective specific gravities of the surface and bottom waters, and of that of the intermediate stratum of 250 fathoms, were found to coincide almost exactly with those previously determined, as the following comparative statement shows:—

	Sp. Gr. Station 39	Sp. Gr. Station 64
Surface	1027·1	1027.1
250 fathoms	1029·3	1029·2
Bottom	1028·1	1028·3

Now the density of the *bottom*-water here corresponds so exactly with that which prevails over the *deeper* bottom of the western basin of the Mediterranean, whilst it so considerably exceeds that of the *bottom* as well as of the *surface* water of the Atlantic, that we cannot fail to recognise it as belonging to the Mediterranean basin; so that, if it has any motion at all, we should expect that motion to be from east to west. Still more certainly may this be affirmed of the *intermediate* stratum, the density of which corresponds with that of the bottom waters of the *shallower* part of the Mediterranean basin; the greatest depth (586 fathoms) at which such water was obtained, being at station 40, the nearest point to the Strait from which a specimen of bottom water was obtained. And it may be further predicated that a stratum of water of a density of 1029·3 could not overlie water of the density of 1028·1, unless it *moved over* the stratum below, that is, unless (1) the two strata were moving in opposite directions, or (2) were moving at different rates in the same direction, or (3) the upper stratum were in motion in either direction, and the lower stratum were stationary. It will presently appear that the second of these conditions is the one which obtains in the present case.

We now proceeded to repeat our experiments with the "current-drag," with the view of obtaining, if possible, unequivocal evidence of the existence of that westerly under-current, which so many considerations combined to render probable. The direction of the wind during this set of experiments was from the east, or opposite to that of the surface-current; and its force (3 to 4) was sufficient, by its *meeting* the current, to produce a considerable swell, which necessitated the employment of a larger boat, and rendered it unsafe to allow her to drift without men. The sectional area of the boat was therefore greater than on the former occasion, giving the in-current a stronger hold upon her; but, on the other hand, the surface she presented to the wind was also greater; and as this acted in the opposite direction, the latter increase might be considered to neutralise the former, or even rather to exceed it, so as to render the boat more capable of being carried westwards by the "current drag," if this should be acted on by an outward under-current. The rate of surface-current was tested as before, and proved to be 1·823 mile per hour, its direction being N.E. by E. ½ E. This was a retardation of more than a mile per hour as compared with the former observation; and that it was not attributable to the mere surface-action of the easterly wind, was clear from the result of the next observation, which showed that the retardation extended to a depth far below the influence of surface-action.—The "current-drag" having been lowered to 100 fathoms' depth, the drift of the boat was reduced to 0·857 mile per hour, or *less than half* its surface-drift; its direction was nearly the same as that of the surface-current, viz., E. by N. ½ N. The "current-drag" was then lowered to a depth of 250 fathoms; and in a short time the boat was seen to be carried along by it in a direction (W.N.W.) *almost exactly opposite* to that of the middle *in*-current of the Strait. The rate of outward movement of the boat was 0·400 mile per hour; but from the considerations formerly stated, it is clear that the actual rate of the under-current must have exceeded that of the boat on the surface. The "current-drag" was then lowered down to a depth of 400 fathoms; and again the boat was carried along in nearly the same direction as in the previous experiments, namely N.W. ½ N.; but more slowly, its rate of movement being 0·300 mile per hour.

Thus, then, our previous deductions were now justified by a *conclusive proof* that there was at this time a return-current in the mid-channel of this *narrowest* part of the Strait, from the Mediterranean towards the Atlantic, flowing beneath the constant surface-stream from the Atlantic into the Mediterranean; and it will be shown hereafter, by a comparison of all the results of our observations, that a strong presumption may be fairly raised for the *constant* existence of such a return-current, though its force and amount are liable to variation.

As the determination of the boundaries of this return-current, and of the amount and conditions of its variation, could

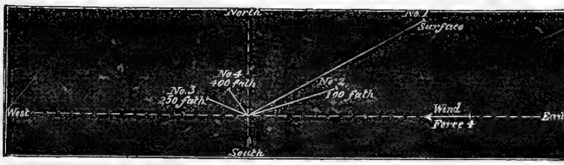


FIG. 1—Rate (per hour) and Direction of Movement of Surface Float, and of Current-Drag at different Depths; with Force and Direction of Wind.

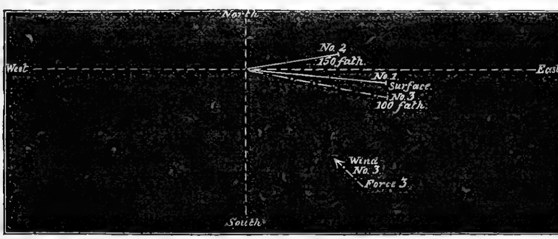

FIG. 2—Rate (per hour) and Direction of Movement of Surface-Float, and of Current-Drag at different Depths; with Force and Direction of Wind in No. 3. (No Wind in Nos 1, 2.)

only be effected by multiplied simultaneous observations a different points, with ample license as to time, neither of whicht fell within the scope of the present expedition, we were obliged to content ourselves, as regards this locality, with what we had found ourselves able to accomplish; and at the conclusion of this day's work we proceeded westwards under easy steam, so as to be able to resume our experiments the next morning in the *shallowest* part of the Strait.

The average surface-temperature of the mid-stream during our outward passage through the Strait proved to be 66°; thus corresponding exactly with what we had found it to be on our inward passage seven weeks previously. This depression, as compared with the surface-temperature of the Strait itself nearer the shore, both north and south, and with the temperature of the Mediterranean to the eastward and that of the Atlantic to the westward, is extremely remarkable. We shall hereafter inquire how it is to be explained.

The breadth of the Channel between Capes Spartel and Trafalgar is about twenty-three nautical or twenty-six and a half statute miles. Its northern half is much shallower than the southern, the 100-fathom line off the Spanish coast running at about twelve miles' distance from Cape Trafalgar; whilst along the African coast it keeps much nearer the hore, being at only two miles' distance from Cape Spartel. Between these two lines, the greatest depth marked in the chart is 194 fathoms; and this occurs off Cape Spartel, at less than a mile from the 100-fathom line. Between this and the opposite border of the deeper channel, the depths vary from 130 to 180 fathoms; the abruptness of the differences at neighbouring points indicating a rocky bottom, of which we soon had unpleasant experience.

SCIENTIFIC SERIALS

IN the *Journal of Botany* for March we find a continuation of the useful catalogue of new species of Phanerogamous plants published in Great Britain during the year 1870, and of Mr. Hiern's paper on the forms and distribution over the world of the *Batrachian* section of *Ranunculus*. Dr. Dickie contributes a paper on the distribution of Algæ, and Mr. A. G. More the commencement of a Supplement to Bromfield's "Flora Vectensis." Short notes, reviews, and reports of Societies fill up the number.

THE *American Naturalist* for February contains several interesting papers. Among them is one on the ant-lion (*Myrmeleo immaculatus*), a Neuropterous insect, by Mr. J. H. Emerton, with drawings of its matamorphoses; one on the resources and climate of California, by Rev. A. P. Peabody; notes on some birds in the Museum of Vassar College, by Prof. Jas. Orton; a short account of the spores of Lichens, by Mr. H. Willey; the Sperm Whales, giant and pigmy, by Dr. Theodore Gill, illustrated with numerous drawings, including the skull of *Callignathus simus* and *Physeter macrocephalus*. The Natural History Miscellany comprises also several shorter papers of much interest, including one on the morphology and ancestry of the King Crab, by the editor, Dr. A. S. Packard, jun.

THE March number of the *Geological Magazine* (No. 81) commences with a long article by Mr. James Croll "On the Determination of the Mean Thickness of the Sedimentary Rocks of the Globe." The author disusses the different methods which have been adopted in order to obtain an approximate estimate of the time occupied in the fo oation of the sedimentary rocks, and remarks that in all these researches it must be borne in mind that, from the continual action of denudation, the existing sedimentary rocks only represent a fraction of the whole thickness of sediments that have been deposited. Taking the denudation of the area of the Mississippi as a guide, he estimates the wearing down of the land at one foot in 6,000 years, and the matter thus removed spread over the bottom of the ocean would produce a deposit one foot thick in 14,400 years. Taking the maximum thickness of British sedimentary strata as calculated by Prof. Ramsay, namely, 72,000 feet, to represent the mean thickness of all the sedimentary rocks which ever have been formed, the author thus gets 1,036,800,000 years as the age of the stratified rocks. Mr. Croll also notices the conditions of the deposition of the sediment carried from the land, and his remarks upon this subject are all worthy of consideration. The editor, Mr. H. Woodward, describes and figures a new Myriopod from the Scotch coal-measures, under the name of *Euphoberia Brownii*, and also some new palæozoic Phyllopod Crustacea, namely *Ceratiocaris ludensis*, a gigantic species from the Lower Ludlow of Leintwardine, *C. oretonensis* and *C. truncatus*, from the yellow carboniferous limestone of Oreton and Farlow in Worcestershire, and *Dithyrocaris Belli*, from the Middle Devonian of Gaspé. He also figures a specimen of *D. tenuistriatus*, McCoy. Mr. De Rance communicates a paper on the occurrence of two distinct glaciations in the Lake District; Mr. John Aitken notices some curious faults occurring in drift at Stockport in Cheshire; and Mr. S. C. Perceval describes the occurrence of Websterite at Brighton.

SOCIETIES AND ACADEMIES

London

Royal Society, March 16.—"Description of *Ceratodus*, a genus of Ganoid Fishes recently discovered in rivers of Queensland, Australia." By Dr. Albert Günther, F.R.S. We shall return to this communication.—"On the Formation of some of the Subaxial Arches in Man." By George W. Callender.

Geological Society, March 8.—Mr. Joseph Prestwich, F.R.S., president, in the chair. Lieut. Lewis de Teissier Prevost and Mr. John Haines were elected Fellows of the Society; and Dr. C. Nilsson, was elected a foreign member of the Society. The following communication was read:—(1) "On the Red Rocks of England of older date than the Trias," by Prof. A. C. Ramsay, LL.D., F.R.S., V.P.G.S. The author stated that the red colour of the Triassic beds is due to peroxide of iron, which encrusts the sedimentary grains as a thin pellicle. This could not have been deposited in an open sea, but rather in an inland salt lake or lakes. The peroxide of iron, which stains the Permian, Old Red Sandstone and Cambrian rocks, is believed by the author to have been deposited in the same manner, in inland waters, salt or fresh. Agreeing with Mr. Godwin-Austen, the Old Red Sandstone was of Lacustrine origin. The absence of marine shells helps to this conclusion. The fish do not contradict it, for some of their nearest living congeners live in African and American rivers. The life of the Upper Silurian deposits of Wales and the adjoining districts continued in full force up to the passage-beds, which mark the change from Silurian to Old Red Sandstone. In these transition strata, genera, species, and individuals are often few, and dwarfed in form. Near Ludlow and May Hill the uppermost Silurian strata contain seeds and fragments of land plants, indicating the neighbourhood of land, and the poverty of numbers and the small size of the shells a change in the condition of the waters. The fish of the Old Red Sandstone also indicate a change of condition of a geographical kind. The circumstances which mark the passage of Silurian into Old Red Sandstone were as follows:—First, shallowing of the sea, so that the area changed into fresh and brackish lagoons, afterwards converted into great freshwater lakes. At the present day marine species are occasionally found living in fresh water, as for example in the Swedish lakes. The same may have been the case in the Old Red Sandstone period. The Old Red Sandstone waters at their beginning are comparable to the Black Sea, now steadily freshening; or the Caspian, once united to the North Sea, if by a change of amount of rainfall and evaporation it freshened by degrees, and finally became a freshwater lake. The Permian strata, to a great extent, consist of red sandstones and marls in the greater part of England; and the Magnesian Limestone of the north of England is also in less degree associated with red marls. These do not occur in the same districts of England, excepting in Lancashire, where a few beds of Magnesian Limestone are interstratified with the marls. The sandstones and marls being red, the colouring matter is considered to be due to peroxide of iron, possibly precipitated from carbonate of iron, introduced in solution into the waters. Land plants are found in some of the Permian beds, showing the neighbourhood of land. No mollusca are found in most of the red beds, except a brachiopod in Warwickshire, and a few other genera in Lancashire, in marls associated with thin bands of Magnesian Limestone. The traces of amphibians are like those found in the Keuper Sandstone, viz., *Dasyceps Bucklandi* and labyrinthodont footprints in the Vale of Eden and at Corncockle Moor, printed on damp surfaces, dried in the sun, and afterwards flooded in a way common in salt lakes. Pseudomorphus crystals of salt and gypsum help to this conclusion. The molluscous fauna of Lancashire, small in number, in this respect resembles the fauna of the Caspian Sea. The fauna of the Magnesian Limestone of the east of England is more numerous, comprising thirty-five genera and seventy-six species, but wonderfully restricted when compared with the Carboniferous fauna. The specimens are generally dwarfed in aspect, and in their poverty may be compared to the Caspian fauna of the present day. Some of the fish of the Marl-Slate have strong affinities to carboniferous genera, which may be supposed to have lived in shallow lagoons, bordered by peaty flats; and the reptiles lately described by Messrs. Howse and Hancock have terrestrial affinities. Besides the poorness of the Mollusca, the Magnesian Limestone seems to afford other hints that it was deposited in an inland salt lake subject to evaporation. Gypsum is common in the interstratified marls. In the open sea limestone is only formed by organic agency, for lime, in solution, only exists in small quantities in such a bulk of water; but in the inland salt lakes carbonates of lime and magnesia might have been deposited simultaneously by concentration of solutions due to evaporation. Some of the Magnesian Limestone strata have almost a tufaceous or stalagmitic aspect, as if deposited from solution. The Cambrian strata also show some evidence of not being true marine deposits. They are purple and red, like the other strata previously spoken of; and the surfaces of the beds sometimes exhibit sun-cracks and rain-pittings. The trilobite *Palæopyge Ramsayi* is considered by the author to be an accidental marking, simulating the form of a trilobite; and the fossils of St. David's are found in grey beds, which may mark occasional influxes of the sea, due to oscillations of level. The foregoing reasonings, in the author's opinion, lead to the conclusion that a continental area existed more or less in the northern hemisphere from the close of the Silurian to the end of the Triassic epoch, and that this geographical continuity of land implies probable continuity of continental genera. There is therefore no palæontological reason why the *Hyperodapedon*, *Telerpeton*, and *Stagonolepis* of the Elgin country should be considered of Triassic age, especially as the beds in which they occur are stratigraphically inseparable from the Old Red Sandstone. Finally, terrestrial and marine European epochs were rapidly reviewed. 1. The Cambrian epoch was probably fresh water. 2. The Old Red Sandstone, Carboniferous, Permian, and Trias were formed during one long continental epoch. This was brought to an end by partial submergence during the Jurassic epoch; and by degrees a new continental area arose, drained by the great continental rivers of the Purbeck and Wealden series, as shown in various parts of Europe. 3. This continent was almost entirely swallowed up in the Upper Cretaceous seas. 4. By subsequent elevation the Eocene lands were formed, and with this continent there came in a new terrestrial fauna. Most of the northern half of Europe since then has been continental, and its terrestrial fauna essentially of modern type. If according to ordinary methods we were to classify the old terrestrial faunas of North America, Europe, Asia, and probably of Africa, a Palæozoic epoch would extend from Old Red Sandstone to Wealden times, and a Neozoic epoch at least from the Eocene period to the present day. The Upper Cretaceous strata would at present remain unclassified. The marine epoch would also temporarily be divided into two, Palæozoic from Laurentian to the close of the Permian times, and all besides down to the present day, would form a Neozoic series. The generic gaps between the two begin already to be filled up. The terrestrial and the marine series at their edges at present overlap each other. The great life-gaps between the two terrestrial periods may some day be filled up by the discovery of the traces of old continents containing intermediate developments of structure as yet undiscovered. Prof. Huxley was pleased to find that the author, on physical grounds, extended some views which he himself had, from other reasons, brought before the Society. He mentioned that there had lately been found in the fresh-waters of Australia a remarkable fish, which had been described, he thought erroneously, as a *Ceratodus*, but which, in many essential characters, was a *Dipterus*, though allied in some respects to *Phaneropleuron*. In other respects it was connected with *Lepidosiren*. It was about to be described by Dr. Günther. The dentition of this fish is curiously similar to that of the Devonian *Dipterus;* and its existence, he thought, corroborated Prof. Ramsay's argument. He agreed with the author as to his views respecting the terrestrial fauna of ancient times, and was quite prepared for the discovery of mammalian remains in earlier formations than those in which they are at present known. He did not so cordially agree with his views as to the marine fauna. He would carry back the forms from which those of the present day are immediately derived to Cretaceous rather than Eocene times. Between the Cretaceous and the Liassic strata there was what appeared to be a middle group, succeeding the Palæozoic. Mr. Etheridge commented on the dwarfed condition of our Permian fauna, which corresponds in the main with that of the Continent, though with fewer genera and species. Prof. Rupert Jones protested against some of the reasons adduced for regarding some of the areas cited as having been inland lakes, though no doubt such lakes must have existed. He thought that mere colour could not be taken as a criterion. If it were, he inquired why the bottoms of the present lakes were not red? Many of the red rocks were, moreover, full of marine fossils. He contended for the true trilobite character of *Palæopyge Ramsayi*, and mentioned its occurrence and that of *Lingula ferruginea* in red Cambrian rocks as proving the marine character of the beds. The Magnesian Limestone he also insisted upon as a purely marine and open sea deposit. Prof. Morris thought the subject required further consideration before the whole of Prof. Ramsay's views were accepted. The Cambrian beds, for instance, containing great beds of conglomerate, seemed such as could only be due to marine action, and would derive their red colour from the decomposition of the old hornblendic gneiss from which they were derived. With regard to the Red Sandstone, he would inquire whether the colour might not be derived from the decomposition of rocks composed of hornblendic materials. The Old Red Sandstone beds, though in this country containing fishes which might be of freshwater genera, had in Russia the same fishes associated with marine shells; and much the same was the case in the Trias. Dr. Carpenter had been led to the conclusion that wherever there was an inland sea connected with the ocean by a strait even of moderate depth, there was a double current tending to preserve some degree of similarity between the waters of the two, the difference of specific gravity in the Mediterranean as compared with the Atlantic being about as 1·026 to 1·029. In the Red Sea, where so little fresh water came in, and there was an evaporation of nearly eight feet per annum, the water was but little salter than that of the ocean with which it was connected. In the Baltic there is an undercurrent inwards, which still keeps it brackish; for otherwise the influx of fresh water was so enormously in excess of the evaporation, that it would long ago have become perfectly fresh. Such facts bore materially on the speculations of the author. Capt. Spratt maintained that in the Dardanelles there was not a trace of such an undercurrent as mentioned by Dr. Carpenter. In the winter months, when the flow of the rivers into the Black Sea was for the most part arrested by ice, the salt water of the Mediterranean was carried into the inland seas, and these being much deeper than the channel of the Dardanelles, the salt water, by its greater specific gravity, remained in the bottom of the sea of Marmora, so that while the upper portion of the water and that on the shores were fresh, marine conditions existed in the deep centre of the sea. Dr. Duncan mentioned that in certain coral reefs intersected by freshwater currents, the corals still continued to be formed; so that the existence of dwarfed forms of corals in ancient times was quite consistent with modern facts. Mr. Forbes commented on the chemical features of Prof. Ramsay's views, and could see no reason why the beds containing iron should not have been deposited in the open sea. Many beds, for instance the Gault, contain more iron than those which are now red, though they may be grey or blue. In sands the grains are often coloured only superficially with iron, probably derived from sulphates. In other cases the sands consist of fragments of rocks already red. There was, in fact, no reason why the beds deposited in the open sea might not subsequently, by oxidation, become perfectly red. Prof. Ramsay replied to the remarks of the various speakers, and summed up by contrasting the usual colour of marine fossiliferous beds with that of the thick, almost non-fossiliferous rocks of which he had been treating

Anthropological Institute, March 20.—Sir John Lubbock, Bart., M.P., president, in the chair. Mr. William Sloan and Mr. John Edward Brearey, of Madras, were elected members. After the adjourned discussion of Mr. Jackson's paper, "The Racial Aspect of the Franco-Prussian War," Mr. Hyde Clarke read a paper "On the Migrations of the Georgians, Circassians, and Amazons, and their connection with the Tibeto-Caucasian race," of which the following is an abstract:—By means of the application of the Georgian, Circassian, and other existing languages *in situ*, the existence of a previous Georgian or Caucasian population was shown, and that the extent of its area was much greater than could have been suspected. This Palæo-georgian language had a much nearer relation to the existing languages than the Hieroglyphic to the Coptic, or the Cuneiform to the Syriac and Persian, but it was in a different and earlier stage of comparative grammar than the Hebrew or Sanskrit, and to which the Caffre group presents some resemblances of structure. The connection of the language with the comparative mythology of the worship of fire and water, gives further evidence as to the diffusion of a population which had held empire over India and thence to the Atlantic shores and these islands. Accepting as a doctrine the conquest of Palestine from the Canaanites and other races identified with the Caucaso-Tibetans, the period of empire would range from 3,500 to 4,500 years ago, during which the germs of the existing civilisation were developed. This population belonged to the family which includes the Tibetan and Chinese stocks. Many portions of the Mosaic record, considered to have been interpolated during the Babylonian captivity, now appeared to be of the greatest antiquity. Many subjects, corollary to the main discoveries, were touched upon, including the connection of the Etruscan, the Phrygian, the languages of Asia Minor, the Akkaa with the Palæogeorgian, also the Lydo-Assyrian rock-cut monuments, the Cyclopean buildings, the so-called Druidic structures, the discovery of metals, &c.

Royal Geographical Society, March 13.—Major-General Sir Henry C. Rawlinson, K.C.B., vice-president, in the chair. The following new Fellows were elected:—Sir James Anderson; W. Blackmore; R. B. Jackson, Sir Donald F. McLeod, K.C.S.I., C.B.; Capt. James Nicol; G. Wm. Petter. The paper read was, "On Mr. Baines's Explorations of the Gold-Fields of South Africa," by Dr. R. J. Mann, and was founded on the voluminous journals, itineraries, astronomical observations, &c., sent home by Mr. Thomas Baines, who had been employed, since the end of 1868, in making a general survey of the gold-yielding country lying between the Limpopo and Zambesi rivers. Leaving the Limpopo at its north-western bend, near the Makloutse and Shapsa rivers, he traversed, with his companions, the range of highlands separating the basins of the Zambesi and Limpopo, in a north-easterly direction, for 300 miles, negotiating with the powerful Matabele chiefs, fixing geographical positions, investigating the mineralogy, and sketching, with his well-known artistic skill, the scenery and people. His farthest point to the north was 17° 30′ S. lat., and in one part of his route he was within 120 miles of the Zambesi. On the route, the heads of a great number of streams were struck, flowing on the one side into the Zambesi, and on the other towards the Limpopo or Indian Ocean, the high land (averaging about 3000 feet) forming the watershed in this part of Africa. The country was healthy, but rather barren and arid, especially on the western slope of the watershed. The chief of the Matabele came to an amicable agreement regarding the working of the gold, which was found very widely distributed over the region, but only in quartz reefs, not in alluvial washing. Many additional particulars regarding the country were given, after the reading of the paper, by Sir John Swinburne, who travelled over most of the same ground, and partly in company with Baines. He said the dry uplands were totally unfit for European settlement, but the well-watered northern and eastern slopes were fertile, and adapted for all kinds of tropical produce. The rich, well-wooded country on the eastern side, rugged with precipitous hills and deep valleys, was inhabited by a superior negro tribe, called *Mashonas*, totally distinct from the invading Matabele of the opposite (western) side of the uplands. Whilst the Metabele—a section of Caffres—follow no arts but those of war, and go nearly naked, the Mashonas are well clothed, and practise the art of smelting and working iron in great perfection. He exhibited a specimen of gold, weighing 27 ounces, extracted by his men from the quartz reefs. Mr. Galton spoke of the great additions made by Mr. Baines, in this journey, to our topographical knowledge of Africa; and Mr. Dunlop stated that quartz had now been found in the country yielding eight and ten ounces of gold to the ton, and that the country was a suitable field for British enterprise.

Linnean Society, March 16.—Mr. G. Bentham, president, in the chair. Col. Grant was elected a fellow.—Prof. Oliver exhibited specimens of *Cupania cinerea*, Poepp. belonging to the order Sapindaceæ, from the Kew Herbarium, in which the seed, partially surrounded by an arillus, splits open, and the exalbuminous embryo falls out, leaving the testa and arillus on the tree, the only instance known of such dehiscence of the seed itself.—An extract was read from a letter from General Munro to Dr. Hooker, describing the vegetation of a little known part of the island of St. Vincent, in the West Indies.—Mr. Henry Reeks exhibited a series of forms of *Aspidium* from Woodhay in Hampshire, which he considered showed a regular gradation between *A. aculeatum* and *A. angulare* of authors.—Notes on *Capparis galeata* and *C. Murrayii*, by Mr. N. A. Dalzell, who believes that these two perfectly distinct species have generally been confounded with one another.—Dr. B. Seemann exhibited a lamellicorn beetle from Nicaragua, one of the largest Coleoptera yet found in America.

PARIS

Academy of Sciences, March 13.—A sharp discussion arose on reading the *procès verbal* of the last sitting. General Morin complained that it was stated by M. Sainte Claire Deville that science had not received proper application in warfare. He was obliged to confess that the French artillery was not up to the times, since they had no steel guns. Steel guns had been condemned as useless by the committee because His Majesty was a great artillerist.—The report of the death of M. Becquerel, sen., during the investment of Paris was stated to be incorrect. It was really M. Dumeril, the son of the celebrated electrician, who had died; M. Becquerel, sen., was not present at the sitting.—M. Leverrier was present at the sitting. M. Dumas read for the learned astronomer a long memoir on the Defence of the Rhone Valley, to which M. Leverrier was attached during the investment of Paris. He resided at Nîsmes and not at Marseilles, as had been said. The principal feature of this work is the construction of an apparatus for optical signalling. This apparatus can be used during day-time, and signals can be seen at a distance of eight miles by day with the naked eye.—M. Serret, President of the Scientific Delegated Commission at Tours and then at Bordeaux, read over a reclamation on behalf of M. Bouccarut, who claims a right to the invention of the instrument manufactured by M. Janssen for guiding aëronauts. M. Serret gave a certificate testifying that M. Bouccarut in the month of September communicated an instrument similar to M. Janssen's compass. If so why did the Delegated Scientific Commission keep the communication without warning the Government of National Defence at Paris, where the instrument was much wanted, as not less than ten balloons were lost, five of them in the sea, because aëronauts were unable to see their way? M. Delaunay read a declaration stating that he acknowledged that Mr. Hennessy had used the same arguments as himself against Mr. Hopkins' theory relative to the fluidity of the interior parts of the earth. But the adhesion given by Sir W. Thomson and other learned men to Mr. Hopkins' views is the reason why he did not regret having again raised this much controverted question.—M. de Fonvielle presented a paper explaining why the gas inside an aërostat very often suddenly increases in density. The phenomenon is common in warm weather when the gas is saturated with vapour from the water of the gasometer, and also when the balloon is rising at a quick rate. The increased density is owing to a quick refrigeration corresponding to the dilatation of the gas when the balloon is ascending to a higher level. It is an illustration of the law of equivalence of *force and heat*. It is the same experiment as is noted in Tyndall's special treatise on that subject, when damp air is placed under an air-pump worked at a certain rate. The movements of the balloon being able to be controlled, it is possible, through an aëronautical ascent, to come to a numerical conclusion.—M. Bouley delivered an interesting lecture on the cattle plague, which is one of the most important topics of the moment. He gave conclusive evidence that it was imported by the Prussian armies. The plague has had really terrific effects in the provinces. On a sea coast the carcasses of infected animals were so numerous that it was impossible to bury them. The authorities were obliged to fill with the putrid cargo old hulks, which were sunk by cannon balls from a distance. He said that infected animals were not unwholesome in their flesh. A secret committee was opened on the question, proposed by M. Sainte Claire Deville.

DIARY

THURSDAY, MARCH 23.

ROYAL SOCIETY, at 8.30.—Experiments on the Successive Polarisation of Light, with the Description of a New Polarising Apparatus: Sir Charles Wheatstone, F.R.S.—On an Approximately Decennial Variation of the Temperature at the Observatory Cape of Good Hope, viewed in connection with the Variation of the Solar Spots: E. J. Stone, F.R S.
SOCIETY OF ANTIQUARIES, at 8.30.—On Flint Implements and other Antiquities from Kent: J. Brent, F S.A.—On Miscellaneous Antiquities from Leicestershire: Rev. Assheton Pownall, F.S.A.
ROYAL INSTITUTION, at 3.—Davy's Discoveries: Dr. Odling.
LONDON INSTITUTION, at 7.30.—On the Colonial Question: Prof. J. E. Thorold Rogers, M.A.

FRIDAY, MARCH 24.

QUEKETT MICROSCOPICAL CLUB, at 8.
ROYAL INSTITUTION, at 9.—Colour: Prof Clerk Maxwell.
ROYAL COLLEGE OF SURGEONS, at 4—On the Teeth of Mammalia: Prof. Flower.

SATURDAY, MARCH 25.

ROYAL INSTITUTION, at 3.—Spirit of the Age: Mr. O'Neil.
ROYAL SCHOOL OF MINES, at 8.—Geology: Dr. Cobbold.

MONDAY, MARCH 27.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.
INSTITUTE OF ACTUARIES, at 7.—On the Equitable Appointment oi a Fund between the Life-tenant and the Reversioner: Andrew Baden.
LONDON INSTITUTION, at 4.—On Astronomy: R. A. Proctor. (Educational Course.)
ROYAL COLLEGE OF SURGEONS, at 4.—On the Teeth of Mammalia: Prof. Flower.

TUESDAY, MARCH 28.

ROYAL INSTITUTION, at 3.—Nutrition of Animals: Dr. M. Foster.

WEDNESDAY, MARCH 29.

SOCIETY OF ARTS, at 8.—On Woman's Work, with Special Reference to Industrial Employments: Miss Emily Faithfull.
ROYAL COLLEGE OF SURGEONS, at 4.—On the Teeth of Mammalia: Prof. Flower.

THURSDAY, MARCH 30.

ROYAL SOCIETY, at 8.30.
SOCIETY OF ANTIQUARIES, at 8.30.
ROYAL INSTITUTION, at 3.—Davy's Discoveries: Dr. Odling.
LONDON INSTITUTION, 7.30.—On Economic Botany: Prof. Bentley.
CHEMICAL SOCIETY, at 8.—Anniversary Meeting.

THURSDAY, MARCH 30, 1871

FIRST REPORT OF THE ROYAL COMMISSION ON SCIENTIFIC INSTRUCTION AND THE ADVANCEMENT OF SCIENCE.

TO THE QUEEN'S MOST EXCELLENT MAJESTY.

May it please your Majesty—

WE, the Commissioners appointed by Your Majesty to make Inquiry with regard to Scientific Instruction and the Advancement of Science, humbly beg leave to present to Your Majesty the following First Report :—

1. We have heard the evidence of witnesses in reference to the following subjects, forming part of our inquiry, viz., the Royal School of Mines, the Geological Survey of Great Britain and Ireland, the Mining Record Office, and the Museum of Practical Geology, at present located in Jermyn Street; and also concerning the Royal College of Chemistry, at present lodged in a building in Oxford Street; which institutions are under one head, entitled Director-General of the Geological Survey of Great Britain and Ireland and Director of the Royal School of Mines.

2. There is no necessary connection between the direction of the Geological Survey of Great Britain and Ireland and the government of the Royal School of Mines.

3. The Royal School of Mines and the Royal College of Chemistry, which practically constitute one School of Pure and Applied Science, are not organised in such a manner as to enable them to perform efficiently the work for which they were originally, or are, at present, intended. We base this conclusion upon three grounds, (*a*) The absence of a chair of Mathematics, (*b*) The absence of Physical or Biological Laboratories in which students can receive practical instruction, (*c*) the insufficiency of accommodation in the Royal College of Chemistry.

4. The officers of the Geological Survey are greatly hindered in their work by want of accommodation; for although their number has been quintupled during the last twenty years, the space originally allotted to them has not been increased.

5. The space allotted to the Mining Record Office is already insufficient for the proper reception and arrangement of the valuable series of documents accumulated there; and for the accommodation of the public who desire to consult them.

6. The collections in the Museum of Practical Geology require greater space for their proper display than is at present afforded.

7. In order to provide a remedy for the inconveniences which have been enumerated, we recommend: (*a*) That the building in Jermyn Street be given up to the Survey and to the Museum, with the reservation that the Lectures to Working Men be delivered as heretofore in the Theatre; (*b*) That the building in Oxford Street be vacated by the Royal College of Chemistry; and (*c*) That the Mining Record Office be lodged with the Statistical Department of the Board of Trade; or, failing accommodation there, in the building now occupied by the Royal College of Chemistry.

8. Without expressing any opinion, at present, as to the policy of Government Schools of Science, your Commissioners, having to deal with the Royal School of Mines and the Royal College of Chemistry as Institutions which have existed for 20 years, and which, during that period, have turned out a large number of well-instructed Students, consider that such steps should be taken as may be necessary to render their Teaching thoroughly efficient.

9. With this object we recommend that the two Institutions be consolidated; that Mathematics be added to the Courses of Instruction now given; and that sufficient Laboratories and Assistance for giving Practical Instruction in Physics, Chemistry, and Biology, be provided.

10. The Institution thus formed (hereinafter called the "Science School") may be conveniently and efficiently governed by a Council of Professors, one of that body acting as Dean.

11. We have further heard evidence concerning the Buildings at South Kensington, now nearly completed, and intended for the reception of a projected School of Naval Architecture and Science; and we recommend that the Science School should be accommodated in these buildings. We have given careful attention to the considerations in favour of the retention in Jermyn Street of the Technical Instruction in certain branches, but we are of opinion that these considerations are outweighed by the great advantages to be derived from concentration.

12. We have further heard evidence concerning the Royal School of Naval Architecture and Marine Engineering, now conducted at South Kensington; and we recommend that the theoretical instruction of that school should in future be given in the Science School, the general instruction in Mathematics, Physical Science, and Mechanical Drawing thus becoming common to both schools. We also recommend that no additional buildings, and no reconstruction of the temporary buildings at present occupied by the Royal School of Naval Architecture and Marine Engineering, should be undertaken, until a further Report has been received from this Commission.

13. We have further heard evidence concerning the system of teaching Elemementary Science under the Science and Art Department; and we are of opinion that the quality of the Instruction given under this Department would be greatly improved if the teachers received Practical Instruction in Elementary Science. Such instruction has, indeed, already been given with marked advantage, although only to a limited extent. The Science School will be available for the instruction of many Science Teachers throughout the country; but we reserve for a Further Report any expression of opinion as to the precise character of such Instruction, and as to the conditions under which it shall be accessible.

14. The organisation of, and accommodation required by, the Science School (including its Technical Branches) and the Royal School of Naval Architecture, will be dealt with in detail in a further Report.

All which we humbly submit for Your Majesty's gracious consideration.

(*Signed*) DEVONSHIRE

LANSDOWNE, JOHN LUBBOCK, J. P. KAY SHUTTLEWORTH, B. SAMUELSON, W. SHARPEY, THOMAS H. HUXLEY, G. G. STOKES, HENRY J. S. SMITH.

J. NORMAN LOCKYER, Secretary

March 9, 1871

THE IRON AND STEEL INSTITUTE

NOTWITHSTANDING the pre-eminent scale on which the mineral and metallic industries of Great Britain are conducted in practice, it must nevertheless be admitted that, as a rule, we have hitherto been long and far behind our continental neighbours in respect to possessing institutions calculated to aid in developing or advancing the scientific or practical bearings of such subjects, or to afford the means of intercommunication between those occupied or interested in such pursuits. To this rule, however, we now have, at least, one honourable exception in the case of the Iron and Steel Institute, now holding its second annual meeting in London, and the establishment of which, in 1869, must be looked upon by all interested in the application of science to the arts, not only as a decided step forward in the right direction, but may even be regarded as inaugurating a new era in the history of the so important iron and steel manufactures of Great Britain.

It has been often the fashion, possibly also with some show of justice, to represent the British manufacturer as a narrow-minded individual surrounded by and, as it were, isolated from even the rest of his own class by a sort of atmosphere heavily loaded with trade jealousy and manufacturing secrets. The experiment of the last two years, however, has amply proved, at least in the iron trade, that it only required the establishment of such an association as the Iron and Steel Institute, to present him in a very different and more favourable light; for the mere fact of bringing together from different parts of the country men all deeply interested in similar pursuits, has at once dissipated the petty jealousy inseparable from a previous state of isolation, and has, besides indicating how much can be effected by combined action, convinced the majority at least, that the interests of the individual manufacturers are intimately bound up with the advancement of the country at large.

The Iron and Steel Institute now numbers some four hundred or more members, including the principal ironmasters and others practically engaged in the production or working of iron and steel, or connected more or less directly with those manufactures by reason of their scientific attainments in metallurgy or the allied sciences; so that, taking into consideration that the Institute has as yet been barely two years in existence, this rapid progress must be regarded as the most convincing proof that a real want for such an association had been very generally felt.

The consideration of what may be termed commercial in contradistinction to technical, questions, such as, for example, those connected with wages, trade regulations, &c., do not come within the sphere of the Institute; the objects of which, besides affording a means of communication between its members, are restricted to the acquisition and dissemination of information, and the discussion of all scientific and practical subjects bearing upon the production and manufacture of iron and steel.

The methods by which these objects are sought to be attained are threefold—viz., by the publications issued by the Institute; the formation of committees to examine into and report upon subjects of special interest; and by general meetings of the members, two at least in each year, one of which is held in London in the spring, whilst the other or autumn meeting is located in the country, in some one of the manufacturing districts, as may be determined by the Council.

The excellent attendance at both the London and the country meetings at Middlesborough and Merthyr Tydvil, under the able presidency of the Duke of Devonshire, as well as in the sustained interest which has been kept up in the proceedings of the Institute, have already proved it to be a success, besides showing how much may be effected by bringing from all parts, into personal contact, those interested in the same occupations, whereby a mutual interchange of ideas and a spirit of generous rivalry is established, which cannot fail to do good to the individual, as well as tend to the progress of the industry of the country at large.

An examination of the publications issued by the Institute up to the present date, will amply justify the assertion that they fully maintain the high position which it aspires to, whether they be judged from a strictly scientific or technical point of view, and that they are entitled to rank alongside any which emanate from even the best institutions of like character on the Continent. For the years 1869 and 1870 they appeared in the form of Transactions; in all seven numbers, which contained the proceedings of the Institute, prefaced by an able inaugural address delivered by its first president, the Duke of Devonshire, who himself is largely interested in iron mines and smelting works, along with a series of well-illustrated papers on various subjects relating to iron and steel-making communicated by members of the Institute.

At the commencement of the present year, however, the Council decided that these Transactions should give way to the more convenient form of a Quarterly Journal, and the first number made its appearance on the 1st of February as a volume of 276 pages, copiously illustrated by well got-up plates, and containing numerous valuable communications to the Institute; as, for example, by Mr. J. L. Bell, on the chemical phenomena of iron smelting; Mr. Siemens on pyrometers; Mr. Kohn on alloys of iron and manganese, &c., whilst in addition to the usual proceedings of the Institute a new and important feature was introduced in the shape of quarterly reports from the two secretaries; the general secretary giving a summary of what has been done in Great Britain in connection with these subjects outside the Institute, whilst the foreign secretary communicates a report on the progress of the iron and steel industries abroad, being an attempt to supply a long-acknowledged desideratum by keeping the public here informed as to what is being done in connection with the production and manufacture of iron and steel in foreign countries.

The present meeting opened on Tuesday with an address from its new President, Mr. Henry Bessemer, so well known in connection with the process which now has effected a world-wide revolution in the manufacture of steel; whilst on the two following days various communications were to be brought forward by Messrs. Bell, Ferrie, Kohn, Tate, Walker, and others, besides a lecture by Prof. Roscoe, F.R.S., on Spectrum Analysis, with special reference to the manufacture of iron and steel.

DAVID FORBES

THE ZOOLOGICAL RECORD ASSOCIATION

A FEW weeks since we announced the establishment of an association for the purpose of continuing the publication of the *Record of Zoological Literature*. Within the last fortnight this new body has been definitely constituted, its rules settled, and a council chosen to manage its affairs. A few words concerning the Association and its objects may, therefore, not be out of place.

The *Record of Zoological Literature* was commenced in 1865 as the private undertaking of its publisher, Mr. Van Voorst, under the editorship of Dr. Albert Günther, F.R.S., who in addition to the superintendence of the whole, himself contributed no small part of the contents of the volume, namely, the portions relating to Mammals, Reptiles, and Fishes. The remaining groups of animals were placed in the hands of Prof. Newton, Dr. Eduard von Martens, Mr. Spence Bate, Mr. W. S. Dallas, Prof. Reay Greene, and Dr. Cobbold. The extreme value of the work to all zoologists was at once recognised by those who became acquainted with it; but, owing to the notorious difficulty of making purely scientific publications known to the persons most desiring them, its sale was limited even in this country, while the high price of the volume kept it almost entirely out of the foreign market. Still publisher, editor, and contributors struggled on, some of the latter even foregoing the scanty pittance they were entitled to receive for their labour. With the third annual volume the undertaking would probably have ceased entirely, but for the generous intervention of the Biological Section of the British Association, which evinced so strong an interest in its continuance that the Committee of Recommendations was prevailed upon to sanction a grant of 100*l.* in its aid—a grant which has since been annually renewed. At the same time, chiefly in consequence of representations made by influential members of the Association, the experiment was made of selling the volume in three separate parts. But this "division of the records" brought no more "comfort" to its supporters than the same process did to the hero of "Locksley Hall;" for the result was that, while no doubt a larger number of zoologists altogether availed themselves of the opportunity of purchasing at a comparatively low price the parts in which they were especially interested, a smaller number of entire copies were sold, and the publisher's loss became so considerable that he positively refused to continue the work.

At this juncture the Zoological Record Committee of the British Association appointed at Liverpool last year, after making several attempts to place the work on a new footing, arrived at the conclusion that the only way of continuing it was by means of an Association with that especial object, and set to work to develop itself accordingly. The process, we believe, was not effected without the normal concomitant symptoms of yelk-cleavage, but these have been got over, and the embryo is now before the world, a promising entity, which, we trust, will, after a little more nursing, maintain an independent existence—for that, of course, is the intention of its producers.

Besides the grant from the British Association before mentioned, aid has been rendered for the forthcoming volume by the Zoological Society of London, in the shape of the interest of a legacy lately bequeathed to the Council of that Society for the furtherance of zoological science, and a very respectable amount of guarantors to the amount of 5*l.* each stand godfathers to the newly-born Association. These consist of nearly all the leading zoologists or well-wishers to zoology of the day, and, glancing over the list, we find upon it such names as assure us that the utmost divergence of views has not hindered their bearers from combining in support of the cause.*

And now a few words as to the objects of the *Zoological Record*, and on the manner in which it has been conducted The enormous range which Biological or even Zoological Science has of late years taken, has produced a correspondingly enormous mass of literature, a compendious knowledge of which is absolutely necessary to every one engaged in the study. Many have been the cases when, after a long and tedious investigation of some abstruse point has been fully or nearly accomplished, the toiling zoologist has found his labours forestalled by some one else, who has been working also in the same direction, and has published the results in some little-known journal mayhap only a short time before. We do not say that such labour is thrown away; but it will be admitted that such anticipation by another is a sore discouragement, and may be anybody's fate. Now, it is one of the main designs of the *Zoological Record* to prevent, so far as it is preventible, this loss of time, and there can be little if any doubt that the publication of an annual volume showing what has been done must most effectually point out what remains to do. An explorer starting off to make geographical discoveries in Africa or the Polar Regions would have little chance of success without knowing what tracts have been already visited. Just then, as the publication of maps or charts is absolutely necessary to produce original geographical researches, so the publication of an annual like the *Zoological Record* is necessary to produce original researches in those regions of Biology to which it refers. The only question is how far the volumes already published have fulfilled their purpose. The recorders, we are sure, are content to have the value of their labours judged by their fellows, and of what nature that judgment is, the unanimous approval of Section D of the British Association is a sufficient test. It must be observed that the ideal "record" of its authors is something more than a mere "report," while it is certainly not a "review." The distinction is somewhat difficult to define, and not easy to maintain. It may be that the recorders, being human, have not always succeeded in maintaining it; but it seems to us remarkable that they have so nearly succeeded. In the first volume this is especially to be observed, and since there was no exemplar before the eyes of the contributors while working, we must attribute this singleness of purpose to the good drilling of Dr. Günther, who originally planned the campaign, wherein he was no less the active man-at-arms than the skilful commander-in-chief. Various changes have been made in the corps of recorders, but of the seven contributors to the first volume four took part in the last, while several recruits have from time to time been enlisted, and the last muster-roll includes Messrs. Rye, Kirby, and Marshall, together with Prof. Percival Wright,—Mr. Spence Bate, Prof.

* To take only a few by way of example, there are Profs. Owen and Huxley, Drs. Gray and Sclater, Canons Kingsley and Tristram, Messrs. Darwin and Jenyns.

Reay Greene, and Dr. Cobbold having retired from the ranks. As regards the future, Dr. Günther, we may state, has resigned the editorship to Prof. Newton, who cannot do better than follow generally in the footsteps of his predecessor, but we are glad to say that the founder will still continue his admirable contributions, for which no one in this country is more fitted. The rest of the administration is not, we believe, definitely settled, but there is little fear that it will not be as efficient as ever, and we wish prosperity to its useful labours.

But before we dismiss the subject, we should like to add a few suggestions, both to the recorders in particular and to the scientific public at large. To the former we would say that as brevity is the soul of wit, so it is of recording. There have been occasions, it must be owned, when this virtue has been disregarded. Let there be no indulgence in "paste-and-scissors-work." It is no doubt a hard and perhaps a dangerous matter to attempt an abstract of what some authors are pleased to term specific or generic "characters"—extending, it may be, over a whole page In such cases by far the best plan would be simply to state that such so-called "characters" are too diffuse for reproduction and too complex for condensation. In this way all chance of misrepresenting an author's meaning—the greatest danger that a recorder has to run—would be avoided, while a gentle hint would be conveyed to a wordy writer that, as it was said of yore, "*verbositas auctoris artis calamitas.*" Of course this treatment should not be practised but on proper provocation, or the recorder will justly be held to be angular rather than angelic, and this last is the character he ought to bear, whether he may ever deserve or not the title of the "Recording Angel." To the scientific public we may declare that the present is an occasion when they ought to come forward and freely encourage the new Association. The chemists, we know, are stirring, and very properly, for a similar annual, and we believe our herbaceous brethren would gladly hail a *Botanical Record.* What chance of getting one so good as by showing that the *Zoological Record* can be made to preserve an existence independent of all grants from scientific bodies, though in its time of nonage such extraneous help was still needed?

OUR BOOK SHELF

The Land of Charity. A Descriptive Account of Travancore and its People. By the Rev. Samuel Mateer, F.L.S. (London: John Snow and Co. 1871.)

THIS book is the result of material collected and observations made during nine years' residence of a missionary in our great Indian empire. Its pages are, of course, chiefly devoted to an exposition of the different forms of worship and belief, and the progress of missionary work amongst the native population; but the author acknowledges the claims of Science by giving three chapters to the Natural History of Travancore and the economic uses of the plants of the country. With regard to the Animal Kingdom, we are told "a curious story of a crocodile which attempted to seize a cow that was grazing near its haunts, fastened to a stake by a long rope. The monster had nearly reached the wooden post before it was perceived by its intended victim. On discovering its danger the terrified cow rushed round and round, and the rope caught the crocodile in such a manner as to wind around its body and the post, so that it was held firmly until seen and dispatched by the owner of the cow." Snakes are, as we all know, very abundant in India, but it is curious to know that in 1862, in Bengal alone, 2,394 persons met their deaths from the bites of these reptiles, and it is further estimated that, throughout the whole of India, not less than 10,000 persons annually die from this cause. Though it is a fact that heaps of Indian plants, having no truly recognised economic or medicinal value, are reputed by the natives to cure snake-bites, our author tells us that no certain specific is known, ammonia being probably the most useful medicine in these cases. The cultivation of the Tapioca plant, which is a native of S. America, seems to be spreading in India. The best Tapioca comes into this country from Rio de Janeiro, but large quantities are also shipped from Singapore, the plant being cultivated in the Straits on account of its commercial value. It appears also to be grown in Travancore, and yields the natives an abundance of wholesome food. In districts where water is scarce, or in times of drought, they almost exist on the roots. It would appear, from the remark made by the author of the presence of a poisonous juice in the roots, that only one species of the Tapioca or Cassava plant is grown, and that the *Manihot utilissima*, Pohl, or bitter Cassava, the poisonous properties of which, however, are thoroughly dispelled by heat.

J. R. J.

The Food, Use, and Beauty of British Birds, &c. By C. O. Groom-Napier, F.G.S., &c., author of "The Book of Nature and the Book of Man," "Tommy Try," &c. New Edition, 18mo, pp. 88. (London, Groombridge, 1870.)

THE author says that his book was, by an eminent living anatomist, termed a "delightful concentrated essence of British Ornithology;" but it appears that the British public were so wilfully blind to its merits that they refused to buy it, for the so-called "new edition" is simply a reissue of the original unsold sheets with a new title-page, a little padding in the shape of "opinions of the Press," and a new preface, to eke out which the Sea Birds' Preservation Act has been introduced. The table of contents, and, still more, the list of errata which were to be found in the old issue, have disappeared from the new one, as also has the photograph representing the author in Mr. Miles's starling-haunted shrubbery. The British public, we think, will ratify their former estimate of this book. A good work might certainly be written on the food and use of birds, and, as we know, many volumes are devoted to the illustration of their beauty, but with all deference to the author of "Tommy Try," we doubt if he is the man for the task.

The Forces of the Universe. By George Berwick, M.D. Pp. 127. (London: Longmans and Co., 1870.)

WHAT could possibly have induced the author to "offer this work to the general public" (preface) we cannot tell, unless we are to attribute it to a "sudden seizure of enthusiasm." These sudden seizures, together with "revolutionary movements," "religious revivals," "insane wars" and "sunstroke," arise, as we find on p. 124, from similar causes, and these, it seems, are more than probably due to "an aberration of the normal molecular action of the nerve-centres, or an increased electrical tension or polarisation of the nervous element in the brain itself."

The aim of the work seems to be an attempt to prove the identity of electrical attraction and the attraction of gravitation. The author confesses that the idea is not original, but we may add that his arrangement, to say the least of it, of the English language certainly is, *e.g.* p. 43—"It has been ascertained that the deeper that we descend into the bowels of the earth, the temperature increases at the rate of," &c. On p. 41, "moreover, the diversified configuration of the earth's surface, formed, as it is, of seas and continents of lands, &c., all which physical conditions having different powers of radiating and absorbing heat, also have the power of causing great local disturbances in this aërial ocean."

It is probably due to a mistake on the part of the printer that the pressure of the air in the latitude of Paris at the level of the sea has risen to 147,304 lbs. per square inch, but we cannot quite account for the statement on p. 39, that the earth revolves daily on its axis "from east to west," or again on p. 12, where common salt is made to consist of sodium and chlorine in "*equal* proportions."

The lines of force in a magnet have often been likened in shape to a double egg-cup, but we doubt if any of our readers have ever seen anything so charmingly *àpropos* as the following similitude. "They (the lines of force) also unite and cross over the equator of a magnet in the same manner that the peripheral nerves of animals decussate over the pons Varolii, and again separate to the opposite hemispheres of the brain." The whole book is written in an absurdly inflated style, such as, for instance, p. 88—"The intensified electricity in these regions will rather pour its fitful beams over the serrated edge of the circular icy continent," &c.; or p. 59—"The blood and the nerves and the muscles that composed his (man's) fabrication (!) moulder into dust, which, in the crucible of time, yields up protoplasm for vegetation." On the last page electricity "carries faithfully the thoughts of men far along the profoundly silent abysses of the deep blue sea." Space, however, compels us to take leave of Dr. Berwick's "bright plateau of cultivated intellectual existence."

LETTERS TO THE EDITOR

Botanical Museums

In your excellent article on Botanical Museums, one point appears to have been overlooked, and to which, with your permission, I should like to call attention. I allude specially to the want of an extensive series of carefully prepared specimens and dissections illustrative of the principal modifications of form and structure to be met with in plants. To the ordinary student of botany, especially to the beginner, a series of herbarium specimens conveys about as much information as a similar collection of postage stamps would do. It is not until the pupil has made some considerable progress that he is in a position to make use of herbarium specimens with advantage to himself for anything more than superficial examination. The supply of fresh specimens in a large town like London is necessarily limited, if not in point of numbers, at least in variety. Would it not therefore be advisable in any future re-organisation of our botanical museums, to meet this want so far as it is possible to do so? A collection, such as I am alluding to, should comprise specimens selected and displayed in such a manner as to show the principal variations in the structure and form of the several organs of plants from the lowest to the highest. It should illustrate, so far as circumstances will allow, the comparative anatomy and physiology of plants much in the same way as the Hunterian Museum of the Royal College of Surgeons illustrates the peculiarities of animal life. In such a museum the system should be subordinated to the plants, not the plants to the system. I am quite aware that in all three establishments to which you call attention some specimens of the kind I refer to are to be found. In the Edinburgh Botanical Museum also are to be seen models and preparations made under the superintendence of Professor Balfour by several of his pupils. It is such specimens as these that for educational purposes it is so desirable to multiply and collect together in a separate department. Where, from the nature of things, such as the delicacy or minute size of the organ or what not, it is not possible to prepare a satisfactory specimen for reference, large models in wax or papier maché might be substituted with advantage. What teacher who has had to initiate the tyro into the complexities of the sphenoid bone or the disposition of the ovules, the structure of the anther, the development of the flower, the arrangements of the flowers in grasses, &c., but has longed for Brobdignagian models whereon to demonstrate the peculiarities of their formation. The organs themselves are often so small, and require so much practice with the use of the dissecting needle before they can be seen by the student, that it is very desirable to aid his preliminary labours as much as possible; to give him, at least, a general idea of what he is to look for in the living specimen. For want of this preliminary help specimens are often wasted by the inexpert pupil, who becomes disgusted because he is unable to see for himself what his books or his teachers tell him he ought to see. A good collection of microscopical preparations should also be provided to illustrate such points as require the use of the compound microscope. Probably the British Museum would be the most fitting place wherein to exhibit such specimens side by side or in conjunction with those illustrative of fossil plants. If some such plan as that hinted at in your article were adopted, we should have the general collections at Kew in conjunction with the gardens and Economic museum, the historical and structural collections at the British Museum, and the Trade Museum at South Kensington. I cannot conclude this letter without adverting to the facilities which exist at Kew for the determination of unknown plants, and particularly of plants cultivated in gardens. Thanks to the admirable arrangements made by former and by the present curator of the herbarium and their assistants, the determination of an unknown plant becomes, comparatively, an easy matter.

Gardener's Chronicle Office, March 27

Occurrence of Glutton near St. Asaph

A CAVE has long been known to exist close to Plas Heaton, the property of Mr. J. R. Heaton, but as it was filled with brown earth nearly to the roof, and the entrance obstructed by large blocks of limestone, it could not be explored without some labour. Mr. Heaton has recently commenced opening it, and, among a large number of bones, has been rewarded by finding part of a jaw, which has been determined by Mr. Boyd Dawkins to be that of a glutton. This is a discovery of very great interest, as occurring in the district where we have already found the remains of reindeer, elk, &c., upon which the glutton principally feeds. The cave is situated on very much higher ground than any of the other bone-bearing caves of the district, and runs down into the hill with the bedding of the rock. Where the other end may be there is as yet no evidence to show, but it promises to be a cave of great extent, and, judging by the festoons of stalactite already arrived at, of great beauty also. Its chief interest, however, lies in the strong probability, from its size and position, that it will contain a very full record of the early natural history of the district, and the first results certainly encourage further exploration.

T. McK. HUGHES

Splendid Meteors

On Saturday evening last, March 25, at about half-past nine local time, I happened to be observing some stars in the eastern quarter of the heavens, when I was astonished by the sudden appearance of a brilliant meteor with a long tail, or streamer, of a reddish hue. The colour of the ball itself was a vivid bluish white. It seemed to start from near ϵ *Virginis*, or a little to the right of that position, and to take a leisurely course in a straight line towards the north under *Arcturus*, α *Coronæ Borealis*, and ϵ *Herculis*, till I lost it behind some houses not far from the northern point of the horizon, if anything, a little to the east of that point. I was most struck with the leisurely pace at which it moved, so different from an ordinary falling star, the velocity appearing to slacken as it proceeded, like that of a railway train after it has passed a spectator. Just when passing under *Arcturus*, the globular head broke up, not unlike one of the fire-balls of a rocket, into a string of five or six luminous beads, getting smaller and smaller towards the tail. The entire length of the meteor seemed to be fore-shortened as it receded towards the horizon. Judging without a watch, I estimated the interval between its appearance and disappearance to be about nine seconds. At the same time a second meteor of inferior dimensions and briefer duration took a somewhat parallel course between *Boötes* and *Ursa Major*.

EDWIN SMITH

Forest Road, Nottingham, March 26

A FEW minutes after sunset on Thursday last (23rd) I saw a very fine meteor in the direction E.N.E.

Its course at first appeared southerly, then, bending downwards, it seemed slowly to drop in a direction perpendicular to the horizon, and I lost sight of it behind a clump of trees. Its light was exceedingly brilliant. J. F. DUTHIE

Leyton, Essex, March 27

Books Wanted

THE only way in which your correspondent of last week, Mr. H. J. Watson, is likely to obtain the volume of the "Annales de Chimie," containing the paper of Braconnot, (not Bracconot, the misprint is Sir John Herschel's), and that of the "Philosophical Transactions" with Dr. Prout's paper, would be to request some second-hand scientific bookseller to place them on his list of "desiderata," so that they may be brought under the notice of those who are likely to have duplicates.

Perhaps Mr. Watson is not aware that there is a good abstract of Braconnot's paper, occupying just over six pages in the *Quarterly Journal of Science*, vol. viii. 1820, and also short abstracts in the *Edinburgh Philosophical Journal*, No. iv. 1820, and Tulloch's *Philosophical Magazine*, vol. lv. 1820. It has also been reprinted into some foreign scientific periodicals, a list of which may be seen on reference to the "Royal Society's Catalogue of Scientific Papers," vol. i.

Oxford, March 24 JAS. B. BAILEY

Measurement of Mass and Force

PROFESSOR EVERETT, towards the close of his much-needed and exhaustive letter in NATURE (March 2) on the Measurement of Mass and Force, proposes to supply an undeniable want in Dynamics by coining the word *kinit* to denote that force which, acting on an avoirdupois pound of matter for a second, generates a velocity of a foot per second. He then adds, "If we substitute gramme for pound and metre for foot, we obtain a different unit which must be called by a different name."

Now one, and perhaps the only, objection to this is that in the face of the rapidly spreading metrical system it seems injudicious and somewhat savouring of retrogression to appropriate the most suitable root at our disposal to designate a force-unit depending upon the *pound* and *foot* (the abandonment of which is now only a question of time), while that based on the gramme and metre is sent a begging. I would therefore suggest to Prof. Everett that a *kinit* (or simply the monosyllabic *kin*) be defined as *that force which, acting on a gramme of matter for a second, generates a velocity of a metre per second;* and then there would follow as a matter of course *kilokin*, &c., suggestively and conveniently denoting either "the amount of force which, acting on a *kilogramme*, &c., of matter for a second, generates a velocity of a *metre* per second," or, "the amount of force which, acting on a *gramme* of matter for a second, generates a velocity of a *kilometre*, &c., per second."

Besides Kinetics and Heat (see NATURE, vol. i. p. 606) there is another department of science where a similar want exists—less pressing, perhaps, as yet, but felt, nevertheless. This is Electricity. Taking as basis Sir W. Thomson's general definition of unit quantity of frictional electricity (*Camb. and Dubl. Mathematical Journal*, March, 1848) a particular unit (*i.e.* a unit dependent upon previously fixed particular units of force and distance) might be chosen, formally defined, and named.

This question of units of measurement and their names appears to me to be anything but trivial. A science, which, by the choice of *one good system of units*, and the adoption of *a suggestive definite and uniform nomenclature*, has put its house in order for the proper reception of the powerful chief Mathematicus, has laid the foundations of true and rapid progress.

College Hall, St. Andrews THOMAS MUIR

The Earthquake

A RATHER severe shock of earthquake was experienced in this neighbourhood on Friday, March 17. The day in question had been remarkably calm, and a heavy suffocating feeling in the atmosphere noticed. About 11.15 P.M. a somewhat loud rumbling noise was heard as if a heavy waggon was passing over pavement; windows, chandeliers, furniture were violently shaken. Cups and saucers made themselves heard, and beds in some cases were distinctly felt to oscillate and heave like a ship at anchor. Breathing in some cases became difficult, but whether from fright or the oppressive state of the atmosphere does not appear. The vibrations were apparently horizontal, and probably in a direction from N. to S., lasting about three or four seconds. Poultry and cage birds showed particular distress by the noise and fluttering which they made. The temperature, which on the previous Tuesday night had fallen as low as 17°, suddenly changed, and the minimum of Friday night was 41°. Saturday morning was remarkably warm; the black bulb thermometer in vacuo reading 92°. The barometer showed no unsteadiness, but had been gradually rising for some days previously. The shocks seems to have been felt from the south of Scotland as far as the north of Derbyshire, much the same account having been received from each locality. THOMAS FAWCETT

Blencowe, Penrith, March 20

THE earthquake recorded for the night of Friday (17th) last was felt here about 11 P.M., distinct vibration being observed by two members of my household.

In support of the theory that shocks are mainly noted along lines of fault, there is a considerable one within a short distance extending northwards for some miles.

CHARLES HENRY MIDDLETON

Lingen Vicarage, Presteigne, Herefordshire, March 23

A SLIGHT shock of earthquake was felt and heard in this neighbourhood at about 9.55 on Monday night last, the 20th instant.

The duration of the shock was not longer than three seconds; it was accompanied as if by a muffled explosion, followed by a slight rumbling of the earth, and a gradual dying away of the sound, which seemed to be in an easterly direction. The last sensation is obviously not very reliable, as much will depend upon the position in which the hearer was sitting.

HENRY COOPER KEY

Stretton Rectory, Hereford, March 23

The Reality of Species

AMONG the many misconceptions that have arisen in connection with the doctrines of evolution appears to be one that species have no real existence. In a recent review (appearing in one of the best London papers) of Mr. Mivart's work, this mistake is strongly expressed, the writer appearing to entertain a profound contempt for anyone who still retains the foolish notion that there is any such thing as a species in nature. Every working naturalist knows well that most assuredly species do exist, and that in the most positive manner, not being conventional merely, but separated from one another in nature by distinct and real characters.

Fortunately for the doctrine of natural selection, it does not in the least question this fact, for did it so, it would be disposed of at once by pointing to a red admiral and tortoiseshell butterfly flitting side by side. It cannot be too distinctly insisted on that natural selection opposes no barrier whatever to the reception of the idea of distinct and separate species. That which it has destroyed is the notion of the constancy of species if the idea of time be set on one side. To argue that species have at the present day no separate existence because they had formerly a common origin, is a foolish confusion. The separate existence of a full-grown and mature animal is not questioned, because at one period it was a bud closely connected with its parent. In point of fact the question of species is really very similar to that of individuality, viewed as a question of origin, the individual and the species are both untenable ideas; but viewed at any one moment, both individual and species are among the most prominent and undoubted facts of our experience. Equally futile is it to argue that species have no existence, because we cannot exactly define what we mean by a species. It is well known that all the efforts of biologists have hitherto failed to produce a satisfactory definition of life. Are we, then, to conclude there is no such thing as a living animal?

The evolutionist contemplates throughout the universe a power underlying all things, indestructible and infinite, most various in its manifestations, always changing and always shifting, but steadily in a given direction, not revealed to man as a separate existence, but known only by its changes and movements, and veiled under the form of matter. Side by side with this universal and unknowable force he sees an opposing power, a tendency in things and matter to be always as they have been, a tendency which the restless force has ever to overcome; but as soon as this has gained its victory, again is it subject to the grasp of its ignoble foe; the struggle, though becoming ever more and more one of detail, is no spasmodic one, though more revealed to us in some phenomena than in others, and more evident at some moments than at others. The questions of the origin, the existence, and the value of species in such a system are easily appreciated. D. SHARP

Thornhill, Feb. 23

The Preponderance of West Winds

IN NATURE of the 16th inst. you appear to contest Mr. Laughton's statement that west winds preponderate over east on the entire globe. I believe that Mr. Laughton is right as to the fact. We have no reason to think that the earth's atmosphere is acted on from without by any force except the sun's heat; if this is the case, the winds can have no effect whatever in either accelerating or retarding the earth's rotation; and, conseqently, the east and west winds must exactly balance each other's effect, for if either were unbalanced it would have an effect, however small, on the earth's rotation. But "an east wind near the equator has more effect in retarding the rotation of the earth, than a west wind of equal extent and force at a higher latitude in accelerating it, just as a weight at the end of the long arm of a lever outweighs an equal weight at the end of the short arm. It is for this reason that the west winds, which are mostly in the higher latitudes, are of greater force, and probably cover a greater area than the east winds, which, under the name of trade winds, predominate near the equator."

This quotation is from a letter of mine published in NATURE of 16th Feb.

In the same number of NATURE there is a letter from Mr. Laughton, maintaining that rain may be caused by fires or explosions. This is confirmed by a fact mentioned by Humboldt in his *Cosmos*, that he once saw an eruption of the volcano of Cotapaxi in the Andes, during which the cone became red hot, and rain fell at an unusual time of the year.

In the same number is a most interesting account of the Winter Meteorological Observatory on Mount Washington in New England. Mount Washington must be much more isolated than mountains 10,000 feet high generally are; and I hope the opportunity may not be lost of making comparative barometric observations, extending over a considerable time, at the summit and the base. In NATURE of 19th January, you published a letter of mine on the importance of such a comparative series.

JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, March 18

Morell's Geometry

IT was with no small surprise that I found myself accused by Mr. J. R. Morell, more than once in last week's NATURE, of having overlooked the fact "that all the proofs in the work ('Essentials of Geometry') are taken from French and German sources." Nothing to my mind could be more obvious than that throughout my review in NATURE for Feb. 23, I was criticising the performance of a compiler. In one instance, indeed—Mr. Morell has surely not already forgotten it—I took the trouble to show *how* Amiot's demonstration of the fundamental properties of parallels had been mutilated by him. I must protest, too, against his claim to freedom from censure on the ground that he has merely copied passages from the works of our highest authorities; for it is about as reasonable as a claim to sanctity would be on the part of one who habitually, it is said, quotes Scripture for his own purposes.

Utterly ignoring the italics which I introduced, to save comment, into his definition of a plane angle, Mr. Morell quotes the Greek of Euclid and the English of Thomson, in justification, apparently, of the aptness of the introduction of the notion of revolution, which no one contested. He compels me, therefore, to draw his serious attention to the fact that neither of these geometers, nor any other to my knowledge, ever confused mankind as he has done by speaking of the "inclination of two straight lines *to a common point.*"

Mr. Morell has, lastly, the audacity to defend his pretended demonstration, on p. 44, of the theorem that two triangles are equal in every respect when the sides of one are respectively equal to the sides of the other, by stating, *first*, that it "is based on the previous pages (42 and 43), overlooked by the Reviewer;" and, *secondly*, that it "agrees almost word for word with Legendre." The first of these statements is absolutely incorrect; on pages 42 and 43, there is not a word upon which the demonstration in question *could* be based. With respect to the second statement, I admit that Mr. Morell's demonstration substantially differs from Legendre's, as given by Blanchet, in Prop. xi. Bk. 1, only by the omission of four words; and to show, by a striking example, what mischief scissors can do in Mr. Morell's hands, I will supply the four missing words, between brackets, in the following reproduction of his demonstration:—

"Let ABC, DEF, be two triangles, having AB = DE, AC = DF, BC = EF, then angle A = D; for if they were unequal, sides BC and EF would be unequal [by the previous proposition]. Therefore A = D."

The fact that Legrendre's most essential previous proposition is *nowhere to be found in* Morell's "Essentials of Geometry," sufficiently accounts for the omission of the four words above inserted. Mr. Morell, however, has yet to realise the fact that these omissions of his have converted a genuine demonstration into a mere assertion, or rather into a flagrant "violation of the most obvious of all logical rules."

Mr. Morell threatens, if space be given him, to show, on his "own authority," that he has "good arguments for what has been advanced." Before he does so let me remind him that logical demonstration, like the multiplication table, is more a subject for direct apprehension than for argument.

THE REVIEWER

A Meteorological Question

WHILE glancing the other day over the article "Meteorology," in the Supplement to the 4th, 5th, and 6th Editions of the *Encyclopædia Britannica*, I was surprised to find under the marginal heading, "Hauhber's Experiment," the following:—"It is conceived that a current of air in sweeping over the surface of the earth, must cease to exert any vertical pressure. But this assumption can hardly be reconciled with any strict principles in science, for the particles of air will not for a moment cease to gravitate, nor will any horizontal motion of them produce the slightest derangement in a perpendicular direction." Is not this a great mistake? QUÆRE

A SUGGESTED NEW DIVISION OF THE EARTH INTO ZOOLOGICAL REGIONS

IT seems now to be generally agreed among zoologists who are specially conversant with the fauna of India, that "the Indian Region" of Dr. Sclater and others can no longer be regarded as a genuine or natural zoological division of the globe, and that India properly so called (from the Himálya to the sea), is rather a border territory where different zoological regions meet and are variously interposed, at the same time blending, as a matter of course, to some extent.*

This is a subject which has long occupied my thoughts, and I am gradually arriving at the opinion that the present dry land upon our planet may be most naturally divided into seven zoological regions, which again are divisible into sub-regions, and these into provinces and sub-provinces.

I. *The Boreal Region*, which is divisable into: 1. Arctic Sub-region, within the confines of the Arctic Circle, but also inclusive of the whole of Greenland, and of Foxland (west of Davis Strait and north of Hudson Strait). 2. Neo-septentrional Sub-region—North America. 3. Neo-meridional Sub-region—Central America with the Antilles. 4. Andisian Sub-region—the chain of the Andes with Chili, Patagonia, and the Fuegian and Falkland Archipelagos. 5. Palæo-septentrional Sub-region—Europe and Asia south of the Arctic Circle, and north of the Pyrenees, Alps, Taurus, Elburz (south of the Caspian Sea), Hindu Kosh, and Western Himálya, extending from the British Islands to Northern Japan? 6. Palæo-meridional Sub-region—the countries adjacent to the Mediterranean, as Africa north of the Atlas (with Madeira, the Canaries, and the Azores), Spain, Italy, Dalmatia and Illyria, Greece, the islands of the Mediterranean and the Levant, Turkey, Asia Minor,

* Vide Mr. W. T. Blanford in the "Proceedings of the Asiatic Society" for September 1867, p. 145 "The fauna of India at the present day is a remarkable mixture of African and Malay forms. The idea, so commonly expressed in European books, of India belonging to the same geological [qu. zoological?] province as the Malay Peninsula and Southern China, is quite erroneous." Vide also the same "Proceedings" for January 1868 p. 18, January 1869, p. 40, and July 1870, p. 238.

Syria, Egypt, Palestine, Mesopotamia, Persia, N. Afghánstân, Pánjâb, Middle China, Southern Japan? 7. Mongolian Sub-region—Mongolia, Tibet, and Chinese Tartary.*

II. *The Columbian Region.*—South America, minus the chain of the Andes and the extreme south. Divided into —1. Brazilian Sub-region; the forest countries east of the Andes. 2. Pampian Sub-region; the Pampas territory. 3. Peruvian Sub-region; Bolivia, Peru, Chili, and the Gallápagos Archipelago.

III. *The Ethiopian Region.*—Africa, south of the Atlas and of Egypt. Divided into—1. Lybian Sub-region; extending from Senegal to Nubia and Arabia, the country bordering on the head of the Persian Gulf (Mekran), S. Afghánstân, Beluchistân, and the desert country of N.W. Hindustân. An outlying strip of this sub-region extends along the cleft, or wady, continuous with the Gulf of Ormuz, in which is situate the depression of the Dead Sea and beyond it the Valley of the Jordan. 2. Nigritian Sub-region; Negroland. 3. Caffrarian Sub-region; Southern Africa. 4. Indian Sub-region; Hindustân proper, or the plains of Upper India E. and S. of the N.W. desert; Dukhun, or table-land of the peninsula of India; and the intervening territory, inclusive of the Vindhaian ghâts; Coromandel coast; low northern half of Ceylon.

IV. *The Lemurian Region.*—Madagascar, the Mascarine Islands, Seychelles, &c. Probably an extensive region of dry land formerly, but now for the most part submerged, where the coral formations occupy so extensive an area.

V. *The Australasian Region.*† The Indo-Chinese peninsula, together with the Indo-Malayan region of Wallace; the southern watershed of the Himályas, at least up to the zone of oaks and rhododendrons, and jungle-clad hill country of Southern India and of Ceylon, if not also certain fertile hill territory in Southern Arabia; Lower and Eastern Bengal; Philippine Islands; Chinese islands of Hainan and Formosa (minus its mountain spine), and probably so much of the south of China as is inhabited by the *Manis* or pangolin, the *Palæornis cyanocephalus*, the genus *Centropus*, and other Australasian and Ethiopian forms. Divided into: 1. Indo-Chinese Sub-region—extending southward over one-half of the Malayan peninsula, as far as Pinang and Province Wellesley; Hainan and lowlands of Formosa, and more or less of the southern part of China. 2. Malayan Sub-region—southern half of the Malayan peninsula, Sumatra, Banka, Borneo, Java, and Bali. 3. Philippian Sub-region (which has Melanesian affinities, as indicated by the presence of a peculiar species of cockatoo—mammiferous animals few in number), Philippine Islands. 4. Himályan Sub-region—the southern watershed of the Himályas, with the *tárai* region at its base, Asám, and Eastern and Lower Bengal (*i.e.* the Sundarbáns). 5. Cinghalese Sub-region—the hilly parts of Ceylon (occupying the southern half of the island), those of southernmost India, and the Malabar ghâts; perhaps also the little-known fertile mountain territory of Southern Arabia, from which Mekka is supplied with grapes and other fruit.

VI. *The Melanesian Region.*—Divided into: 1. Australian Sub-region—Australia (minus York peninsula and part of Queensland), Tasmania. 2. Papuan Sub-region—Papua, New Britain and New Ireland, Jilolo or Halmahira, Ceram, Buru, Moluccas, Aru Islands, and Timor Lât; Louisiade Archipelago; York Peninsula and eastern half of Queensland (as far as the dividing range) on the mainland of Australia. 3. Celebesian Sub-region—the very remarkable island of Celebes, which has Australasian affinities, but subordinates to the present region: Islands of Lombok, Sumbáwa, Flores, Wetter, Timor, and Sandalwood Island. (Austro-Malayan region of Wallace.) 4. Antarctic Sub-region, inclusive of Kerguelin's Land.

VII. *The Polynesian Region.*—Divided into: 1. Moarian* Sub-region—New Zealand, with the islets appertaining to it, inclusive of Macquairie Island (upon which far southern land a peculiar species of ground-parrakeet inhabits, of a Polynesian genus—*Cyanorhamphus*). 2. Polynesian Sub-region—comprehending the Archipelagos of the Pacific, excepting those which appertain to the Columbian region.

All of these Zoological Divisions of the dry land upon the surface of our planet might be amply illustrated by an enumeration of the species and genera, or even higher groups, which are respectively peculiar to them. Thus, the presence of the true raven (*Corvus corax*) exactly coincides with the limits which are here assigned to the vast Boreal region, even to the Indian Pánjâb, and assuming that the so-called American species (*C. carnivorus* and *C. mexicanus*) do not really differ, which I believe to be the case, as likewise the so-called *C. tibetanus*; the sole exception being that of the Andisian sub-region, inasmuch as there is no *Corvus* in all South America. Be it always remembered that the major and the minor continents approximate in the Northern Pacific, to say nothing of the connection between them afforded by the chain of the Aleutian islands, and that a remarkable wild mountain sheep (*Ovis canadensis*) inhabits both sides of the Pacific, and not only the peninsula of Kamchatka, but the Stannavoi mountains which lie west of the sea of Ochotsk.

The southern watershed of the Himálya (below at least the zone of oaks and rhododendrons) consists, decidedly, of an extension westward of the Australasian

* It may seem a bold idea to put forward, but I have an exceedingly strong impression that the Stannavoi mountains, and the country eastward of them, the Valley of the Amur and all Mantchuria, with the Korean (or Koriak?) Peninsula, the country of the Tchuktchi who, though pastoral, are veritable Eskimo, (I adopt the spelling of Sir J. Richardson), the peninsula of Kamchatka (as Mr. F. Whymper spells it), the Kurile Islands, the Japanese Archipelago in part, and the Island of Saghalian or Sankhalin, which separates the Gulf of Tahtary from the Sea of Okhotsk, together with the Alaska territory, *eastward* of Bering's Straits (constituting part of the mainland of America) appertain alike to my Neo-septentrional sub-region, however the area may be subdivisible into provinces and sub-provinces; the Palæo-septentrional, the Neo-septentrional, and Arctic sub-regions being there variously interposed, with a certain amount of blending as in all such cases. Be it remarked that the *Ovis canadensis* is identical on the Stannavoi Mountains, those of Kamchatka, and the Rocky Mountain chain in North America; also that the insectivorous genus *Urotalpa* (even the species apparently) is identical in Western North America and Japan, and there are very remarkable ethnological affinities pervading the entire area, to which it is sufficient here thus cursorily to allude. Indeed, the Japanese themselves are more nearly akin to the Columbians (or redskins, the so-called "American Indians") than to the Asiatic nations of pronounced Mongolian type, to which latter the Eimo of Yeso and kindred Kamchatkadales strictly appertain. The *Ovibos moschatus* (or musk-sheep) is asserted to exist on the Island of Saghalian! May not the species prove, however, to be *Ovibos Pallantis* of De Blainville, supposed hitherto to be extinct, rather than *O. moschatus* of the Arctic-American Barren-grounds? If I mistake not (writing from memory) the *O. Pallantis* is identical with the North American *Böotherium bombifrons* of Trans-Atlantic palæontologists. *O. moschatus* would appear at one time to have been distributed over my Palæo-septentrional sub-region even to the area now constituting the British islands. The present Arctic sub-region must at that time have been co-extensive with the existent Palæo-septentrional if not also the existent Neo-septentrional sub-regions. Together with *Ovibos moschatus* on the Arctic American Barren-grounds, the European and Asiatic *Ursus arctos* there exists, which is significant of a former connection with the major continent! The Barren-grounds physically resemble the "Tundras" of Siberia and likewise mountain Lapland. The more that I reflect upon what is known of the fauna and flora of the debatable land in the extreme N.E. of Asia, the more thoroughly do I feel convinced that the Stannavoi mountains constitute the true and real boundary between Asia and America. Southward of the Stannavoi mountains, in Mantchuria, the two continents blend. The Japanese archipelago belongs to America, and not to Asia; at least in great part, as indicated by the presence of the *Urotalpa*; but there is also a true *Talpa* indicative of both Palæo-septentrional and a Palæo-meridional relations, and *Phasianus versicolor* and *P. Söemmeringii* indicate the latter, while many of the insessorial birds of Japan indicate the former, and the bulbul of the genus *Microcelis* indicates an Australasian element, so that the Japanese Archipelago is, after all, a debatable land where different zoological regions and sub-regions meet and blend more or less: *Cervus pseudaxis* of the mountain spine of Formosa, so nearly akin to the much smaller *C. sika* of Japan and the much larger *C. mantchuricus* of Mantchuria, again indicating the propriety of recognising a Japanese or Korean province of the Neo-septentrional sub-region of the grand Boreal region. All qualified botanists will surely bear me out in this opinion.

† Austral-Asia as distinguished from Australia: approximately the same as "the Indian region" of Dr. Sclater, but shorn of the greater part of *India* properly so denominated.

* I propose Moaria rather than Maoria, following Dr. Sclater's example of Lemuria; naming the land from the indigenous "moa" genus (*Dinornis*) rather than from the present Maori inhabitants. Of course, it is well known that in the Polynesian languages "moa" merely signifies a fowl: but it has become specialised since the discovery of the extinct *Dinornis* genus by Europeans.

region, and in the bird-class its connection with India is maintained chiefly by migratory species; and very many of the permanently resident species, which have been thought to be specially characteristic of the Himálya, are equally found more or less throughout the Indo-Chinese sub-region, and not a few of them even in the Malayan sub-region, although nowhere met with in India, properly so called (the extensive *Liothrix* series of birds, for instance), while a few of them reappear as the same or as closely proximate (little altered) species in the hilly parts of Southern India and of Ceylon. On the other hand, as may be generally remarked of bordering sub-regions of different regions, there are some cases of mutual representation in the Himályan sub-region of the Australasian region, and the Indian sub-region of the Ethiopian region. The lángur monkey (*Presbytes schistaceus*) of the Himálya; is thus a specialised form of the hunumân group of India, exemplified by the Bengal hunumân (*P. entellus*) and others, this being a characteristic Indian division of the genus which has no representative eastward of the Ganges.

India, properly so called, is a land where sundry sub-regions appertaining to different regions meet, and are variously interposed. The Palæo-septentrional sub-region of the Boreal region extends into the Pánjâb, while the Mongolian sub-region borders upon the S.E. Himálya; the southern flank of the Himálya constitutes the Himályan sub-region of the Australasian region, to which, perhaps, should be referred (as distinct provinces) the mountains of Southern India and of Ceylon; then the Lybian sub-region of the Ethiopian region extends as far as the desert country N.W of Delhi; and the rest of India, with the low northern half of Ceylon, constitutes the main part of the Indian sub-region of the Ethiopian region. The N.W. Himálya again passes northward into the Palæo-septentrional and southward (in the alpine Pánjâb) into the Palæo-meridional sub-regions. In a S.W. direction the Máldive and the Láccadive coral-islands belong strictly to the Lemurian region of Dr. Sclater, and I am not sure that the latter does not reach the mainland of India, to comprehend the Concan or low maritime country constituting the Malabar coast, and lying along the foot of the ghâts. India, therefore, instead of being the nucleus of a distinct zoological region, is a land of extraordinarily complex zoological affinities.

As regards North America, it may be observed that the migratory insessorial birds are of Columbian types, whereas the permanently resident species are of types cognate with those of corresponding latitudes in the major continent: as we likewise find, in Europe, that our feathered summer visitants are of tropical or juxta-tropical forms, as exemplified by the roller, bee-eater, cuckoo, oriole, and the mass of small insectivorous genera; and the same has already been remarked with reference to the Himálya, viz. that as concerns the bird class, the connection of the southern flanks of the Himálya with the plains of India is chiefly maintained by the species which migrate to and fro. Among the gallinaceous birds of North America, the turkeys (*Meleagris*) are the only fowls which have spurred tarsi, indicating their affinity to so many of the major continent genera of poultry-birds, while the partridges of the same sub-region (*Ortyx* and *Lophortyx*) are not more different from major continent forms than are many of the latter from each other. The turkeys are assuredly not more peculiar in any respect than are the peafowl and the tragopans (*Ceriornis*) of Asia, and the same holds true of the North American colins or partridges, even admitting the affinity of the latter for the *Odontophori* of South America. The northern continent, however, has nothing corresponding to the curassows and guans (*Cracidæ*), or to the tinamou (*Tinamidæ*) of the Columbian region, to its great family of toucans (*Rhamphastidæ*), motmots (*Momotidæ*), jacamars (*Galbulidæ*), puff-birds (*Bucconidæ*), cariámas (*Cariamidæ*), trumpeter-birds (*Psophiidæ*), or its nandous (*Rhæidæ*); and of the enormous family of humming-birds (*Trochilidæ*) it has only some four or five species as seasonal immigrants! Again, in the class of Mammalia it has no living representative of the *Edentata*, so characteristic of the Columbian region (though it did formerly possess the *Megalonyx*), nor of the marsupial true opossums (*Didelphidæ*), save one species only in the southernmost Atlantic States of the Union; but it has a fair proportion of *Insectivora*, which in South America the *Didelphidæ* completely replace. The rodent families *Chinchillidæ* and *Caviidæ*, I look upon as Andisian forms, even though the viscacha (*Lagostomus tetradactylus*) represents the former in the Pampian sub-region of the Columbian region. The mammalia of the Neo-septentrional sub-region of the Boreal region are surely not more different from those of the Eur-Asian sub-regions of the same region than are those of the latter from one another, say the Mongolian sub-region from either of the rest. With regard to the Andisian sub-region, I am mainly induced from a consideration of its extinct mammalia (so different from those of the Pampas) to consider it as a southern extension of the American portion of the grand Boreal region, and especially from the occurrence not only of such an animal as the *Mastodon andium*, but also of the living llámas and alpácas (*Auchenia*), which have no other known kindred, existent or extinct, than the camels of the major continent. Nevertheless, as usual in bordering sub-regions of different regions, there is an interposition of forms to a certain extent, as illustrated, on the one hand, by the existence of the viscácha on the Pampian sub-region of the Columbian region, and by that of the edentate *Chlamydophorus truncatus* in the Andes.

The Neo-meridional sub-region of the Boreal region has much stronger affinities for the Columbian region upon which it borders than has the Palæo-meridional sub-region of the Boreal region for the Ethiopian region and for the Australasian region upon both of which it borders, which of course is attributable to its nearer proximity to the Equator bringing it within the influence of the tropical and periodical rainfall. The several regions which are subject to that rainfall in different meridians hold relations of analogy with each other, *i.e.* the Nigritian sub-region of the Ethiopian region, the Lemurian region, the whole Australasian region, the Celebesian and the Papuan sub-regions of the Melanesian region, and the Peruvian and Brazilian sub-regions of the Columbian region. Then, southward, in corresponding latitudes beyond the influence of the tropical rainfall, the same analogies hold between the Andisian sub-region of the Boreal region, the Pampian sub-region of the Columbian region, the Caffrarian sub-region of the Ethiopian region, and the Australian sub-region of the Melanesian region; while, again, south of the parallel of 40° S. lat., the analogies (though still considerable) between the Patagonian sub-region and those parts of the Australian sub-region and the Moarian sub-region which fall within the boundary indicated are, to some extent, less prominently marked. *Ptilopachus* and kindred strong-footed passerine birds in Patagonia, nevertheless, most readily call to mind *Menura* and *Orthonyx* in Australia, and *Mohoua* in Moaria or New Zealand.

Having submitted these views I reserve for another occasion the consideration of other classes of the animal kingdom; premising, however, that I am well aware of such facts as the utter absence of the *Cyprinidæ* (or carp family) in all America eastward of Bering's Straits, a group of fishes which is so immensely developed in S.E. Asia. So far as the classes of mammalia and birds are concerned, I think that I have about hit upon the true classification of zoological regions, and I wish, before returning to the subject, to avail myself of the critical remarks of competent naturalists having reference to all classes.

E. BLYTH

THE PLANET JUPITER

SINCE the earliest days of telescopic investigation, there has never been a period in which this magnificent planet has been subjected to such an extended scrutiny as the present. Telescopes of all sizes and powers, and eyes of all degrees of sensitiveness and accuracy, are being directed night after night—or rather would be so, but for the proverbial uncertainty of our English climate—towards the splendid gem of the south-eastern heaven. Such is the natural result of that unexampled diffusion of a taste for astronomy, and of the equally unprecedented multiplication of telescopes of considerable pretensions, which is characteristic of the present time, and which is so gratifying to the lovers of physical science.

This state of things, however, it need not be said, does not date from the present apparition of the planet. It is merely a renewal of the attention which was directed to the same object during the preceding winter, and it is the character of the results obtained during that former period, which has led to the ensuing remarks.

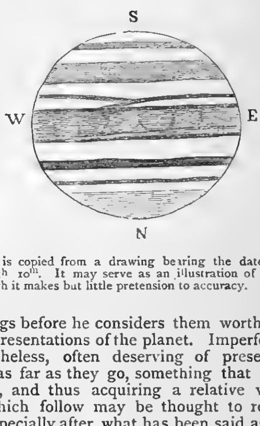
It may be reasonably thought that a comparison of such drawings as are generally attainable, professing to represent the planet during its late appearance, is not very satisfactory; and that greater agreement might fairly have been expected. Every observer must be presumed to have done his best: yet deviations exist of no inconsiderable magnitude. There must be some reason for these discrepancies; and it will be worth our while to inquire into their nature, while, at the same time, we would carefully avoid anything like an implied depreciation of any individual result.

In the first place, as regards colour, there is little difficulty in seeing that a considerable margin must be left for uncertainty. We meet with unpleasant statements from time to time as to the prevalence of colour-blindness, or at least what might be called colour-perversion, or colour-partiality, in some modification or other, to a greater extent than might have been supposed. And independently of this, there may be some dissimilarity of tint in images formed respectively by the achromatic and the reflector, though perhaps less than some persons might expect; since the blue rays which usually go astray in the former instrument are also absorbed by the silver film of the latter, so that there will be a prevailing complementary orange, however feeble, in the light that forms the image in either case. There will, however, be this advantage—and a considerable one—on the side of the reflector, that the blue light, in place of forming an unpleasant fringe, entirely disappears, leaving a delightfully colourless field in the use of the higher powers. Refractors may also differ somewhat in their mode or degree of correction, and consequently in the uncompensated tint; and in either construction eye-pieces may be chargeable with deficient achromaticity. So that on the whole we can scarcely be surprised at some differences in the results as far as colour is concerned.

But there would seem to be other and more influential reasons for the want of correspondence, as affecting form and position. One may be that all observers do not *see* equally well: not referring by this expression to clearness of eye, though in this there may be many degrees, but to the habit of attention. Where one man, for example, merely notes concerning three or four objects that they are not all of the same size; another will almost instinctively estimate their proportionate difference in magnitude. One observer again may be impressed with the proportions of the objects, but may miss those of their mutual distances: nor, again, are the estimates of different observers equally entitled to confidence. There are eyes, too, very good ones for other purposes, which are less successful than would have been expected in the discrimination of minute planetary markings, a fact not easy of explanation.

But besides this source of discrepancy, another exists in the fact that all observers do not draw equally well; or rather it may be feared that but few draw well at all. It is much to be regretted that a certain amount of artistic skill is not considered absolutely necessary in a liberal education; the advantage and pleasure derivable from it in after life are so obvious that it may well be questioned whether some of the time that is spent in mastering classical and mathematical niceties of an extremely unserviceable and unpractical nature, might not be better expended in the acquirement of the most useful art of design. It ought to be remembered, also, that not only a general facility in observation and delineation is requisite, but that something depends upon that special training which results from familiarity with the individual object. Even a careful observer, whose attention had been chiefly turned to objects of another kind, might not recognise as much of planetary markings at first, as after he had studied and learned their character; and on the other hand, a competent artist might produce inaccurate work during his early acquaintance with the telescope, simply from the unfamiliar aspect of what he has to represent, as compared with anything which he has been accustomed to delineate.

When, therefore, all these sources of discrepancy are taken into account, the differences in instruments, in eyes, in hands, and in experience, it is no longer matter of surprise that the results already obtained with regard to this planet are less satisfactory in points of mutual agreement than would have been desirable. It may be hoped, and to a certain degree expected, that we shall do better in future. Inexperience is a fault that will disappear of itself; and it would be well if the unpractised observer would be content to expend a little time and trouble in making tentative drawings before he considers them worthy of taking rank as representations of the planet. Imperfect attempts are, nevertheless, often deserving of preservation, as recording, as far as they go, something that may not be seen again, and thus acquiring a relative value. The remarks which follow may be thought to require some apology, especially after what has been said as to some of the causes of discrepancy; but it is hoped that their purport will not be misapprehended. It is well known that success in observation is much more readily obtained by those who have some previous idea as to what they may fairly expect to see; and on this ground the ensuing suggestions may be permitted, as the result of considerable familiarity with the object. They claim no higher character than suggestions—open as freely to contradiction as confirmation; and their object will be accomplished if they are found to give some aid to the unpractised amateur; the skilled observer will forgive them if he finds them needless, or correct them where they may be in error. They are deduced from the observations of forty-three nights, from 15th October, 1869, to 4th April, 1870, in the use of a With silvered glass speculum of $9\frac{1}{3}$ inches



This sketch is copied from a drawing bearing the date of 1870, December 14^{d} 11^{h} 10^{m}. It may serve as an illustration of some of these remarks, though it makes but little pretension to accuracy.

aperture and power most frequently of 212.* For the sake of convenience we may call the dark streaks *belts* and the luminous ones *zones*; and we may divide the disc into three portions—the equatorial, the northern, and the southern region.

The equatorial region may be described as a coloured girdle surrounding the planet, and consisting of two belts with a lighter space included between them. The relative proportion of these belts—the edges of the girdle—seems not invariable, and should be noted. Especial attention should be paid also to the tint of this region, as a diminution of intensity is suspected. The centre of the girdle is one of the most interesting portions of the disc, containing a number of dark markings projecting into it from the S. (upper as inverted) border, but not reaching the opposite N. edge, and taking the form of the piers of a bridge, or, when more fully developed or perfectly seen, of festoons, in which lighter yellow elliptical areas are included. For atmospheric phenomena, as these appear to be, they maintain a singular degree of uniformity and persistency, although their dimensions seem to vary, on different sides of the globe. An examination of earlier drawings, some of them in private hands, which I have been permitted to inspect, shows that, although at present conspicuous chiefly in the equatorial region, they are by no means restricted to that portion of the planet's surface. And here it may be noted that for the due comprehension of these details, especial attention should be paid to the laws of perspective. The *foreshortening*, as it is technically termed, of the regions approximating to the planet's limb, has a great influence on the apparent form of every marking lying in a meridional direction, while the ordinary belts are entirely unaffected by it. In all probability our familiarity from early youth with the common maps of the globe in two hemispheres may tend to preoccupy us with erroneous impressions in this respect, the exterior portions of those hemispheres being projected on an entirely artificial system, which exhibits them as little foreshortened as may be, and consequently extremely unlike their natural appearance on the globe. For any one unacquainted with perspective, it would be worth while to compare the edges of such a map with the corresponding portions of a terrestrial globe, as regarded from one point of view; or a globe being surrounded with a strip of paper bearing a number of equidistant markings, it will be instructive to notice the wide change in their aspect as the globe is made to rotate on its axis. To this foreshortening, it may be noted, rather than to atmospheric obscuration, as has often been alleged, we may ascribe the invisibility of many features of the planet in the neighbourhood of the limb; the existence of an external hazy envelope may be probable, but the fading of the belts at their extremities, which has often been referred to in this light, cannot be considered conclusive; for it is remarkable that as telescopes have been improved, this alleged fading has been less spoken of. It is not at all shown in the finest drawing hitherto published (that by De La Rue), in the use of an instrument of the most critical defining power; and with my nine-inch speculum it is so doubtful under favourable circumstances that I should not have independently noted it. Attention might well be given to this point, as if a difference should be found with the same eye and telescope in different seasons, it would plainly suggest atmospheric variation.

The northern region commences with a very luminous zone, to my eye the brightest and whitest part of the disc, and usually free from interruptions. Next to this comes a belt of remarkable intensity and permanency, from the edges of which dark but short markings have been, though rarely, seen to project. Its colour formed an uniform contrast with the equatorial belts during the last season; but I have thought this less striking recently. This great belt is commonly divided on the north side by a narrow light zone from a small thin companion of uncertain aspect, and during the present season not invariably parallel to its overpowering neighbour; sometimes, it is a mere edging to a streaky cap reaching to the pole, at others, a light stripe intervenes.

Passing now to the other side of the central girdle, we find next to its south border a region of some breadth, less luminous and much less tranquil than the corresponding north zone. It is interrupted by a belt of variable position and aspect, sometimes very feeble and narrow, at others a rival or more to the neighbouring edge of the central girdle. Its origin lies so close to this latter belt that it almost seems to branch out from it, and last season it followed an independent, and, in part, slightly spiral track round the greater part of the globe before its disappearance; at present I have not been able to trace its whole course, but I see that some remarkable changes have taken place. In this zone lay last winter the very curious elliptical marking described by Gledhill and Mayer, but not, I believe, by others. I never saw it, though it must have been repeatedly before my eyes—a valuable caution to myself and other students—for I had supposed myself too familiar with every portion of the disc to have overlooked so singular a feature. It is possible that my failure may have arisen from my having omitted to stop off the extreme margin of my speculum, which lies quite open in its cell without any rim. I had been repeatedly requested to do so by its accomplished maker, but from want of leisure and some difficulty in the arrangement had neglected it till near the close of those observations, when the evident improvement of definition made me regret that I had recourse to the expedient so late. This precaution, which is requisite with all open specula, is in the ordinary mode of mounting rendered needless by enclosure in a cell.

South of this changeable region lies a grey belt of uncertain form and extent, sometimes divided in two, at others partially interrupted by white spots. Between this and the south pole another belt is occasionally seen, and I have thought the colouring of this and the corresponding north area, not identical. The extreme foreshortening of these regions, and the nearly vertical position of the planet's axis, must ever prevent us from obtaining much knowledge of a wide tract surrounding either pole. The north pole is at present the one more exposed, not only to our view but to solar influences; and it may be worthy of notice that there is some existing dissimilarity in the aspect of the two hemispheres. An axial inclination of little more than 3° would indeed cause but little variety of season on the earth; but with the very dissimilar constitution and condition of Jupiter we know not how much may be effected by its influence.

These suggestions need not be carried into further detail. We shall however note, for the benefit of those who are little accustomed to the object, that the optical changes produced by rotation alone are such that we must be on our guard against being misled by their extent and rapidity.

T. W. WEBB

* The results have already been given in detail in the *Popular Science Review*, July 1870.

NOTES

WE have received the first Report of the Royal Commission on Scientific Instruction and the Advancement of Science just as we were going to press. We therefore let the Report, which we print elsewhere, speak for itself. We observe that it is signed by all the Commissioners, and we trust that it is the earnest of other, equally if not more important, ones to follow.

WE are informed that the future of the Kew Observatory is now being considered by the Kew Committee. We would ask whether the occasion is not a fitting one to bring before the Royal Commission on the Advancement of Science, which is now sitting, the disgraceful state of this country in the matter of such institutions as Kew. All true and disinterested lovers of science would certainly second anything the Kew Committee might urge as to the importance not only of the retention of the Observatory in its present functions, but also of a considerable expansion of them. We fearlessly express the opinion, that in England the attempt to carry on researches "of long breath" by private effort has signally failed, and the sooner this is acknowledged by scientific men the better. Our remark does not apply only to such researches even, for on all sides, in all branches of knowledge, we are conspicuous from our prominent position in the rear. It is not right that in England we should simply teach what Germans and others have discovered.

WE greatly regret to have to record the death, at Vienna, of Prof. Haidinger, the eminent mineralogist. Next week we hope to give a sketch of his life.

WE have already announced the proposed formation of a Society of Biblical Archæology. The Society has now been organised, and the following papers will shortly be read, or are in progress:—On the relations of the Assyrian and Scriptural Chronology; by Sir Henry Rawlinson, K.C.B., &c. On an Eclipse mentioned on the Assyrian Tablets, hitherto unidentified; by Mr. H. Fox Talbot. On the Medical Science of the Ancient Egyptians; by Dr. S. Birch. On the Invasion of Egypt by adjacent Nations in the time of Menephthah I.; by Dr. S. Birch. On the Ancient Connections of Egypt and Assyria; by Mr. G. Smith. On Ancient Chaldean Inscriptions and their History; by Mr. G. Smith. On the Caverns under Jerusalem; by Mr. W. Simpson. On the Flora of Palestine; by Mr. B. T. Lowne. On the Sarcophagus of Oimenephthah I. (Sethos I.); by Mr. Joseph Bonomi. We give in another column a report of the inaugural meeting held on the 21st inst.

WE learn from our Paris correspondent that the leaders of the insurrection have suspended the publication of the *Comptes Rendus*, and have dismissed M. de Parville, the scientific editor of the *Journal Officiel*. Public libraries and scientific institutions are mostly closed, but the museums and galleries have not yet been pillaged. It will be seen, however, from our report in another column that the *Académie des Sciences* continues its sittings with uninterrupted regularity.

WE have received a parcel of numbers of the *Révue des Cours Scientifiques*, the publication of which was also maintained during the Siege of Paris, though not with the same regularity as the *Moniteur Scientifique*. The numbers to hand contain many interesting articles on the supply of food, hygiene, surgical science, and other subjects incident to the state of siege.

A SCIENTIFIC institution has, we learn from *Harper's Weekly*, lately been organised in the city of Washington under the name of the Washington Philosophical Society, the object of which is to furnish to the many persons interested in science, and resident in Washington, the means of convenient communication with each other, in order to exchange discoveries and observations in different branches of learning. Many organisations with the same end in view have been started at various times in Washington, but have not been very successful in accomplishing their purpose, partly on account of the ambition of the founders in endeavouring to give to them too much of a national basis, and partly because the time was not entirely ripe for such an enterprise. It is believed that the prospects of the success of this new society are very good, as Washington possesses, at the present time, a larger number of specialists in the different departments of science than is to be found in any other city in the United States. This is easily accounted for when we bear in mind that the Coast Survey Office, the Patent Office, the Agricultural Department, the United States Medical Department, the Smithsonian Institution, the Library of Congress, the National Observatory, the Scientific Bureaus of the War, Navy, Treasury, and Interior Departments, and other public bodies, all established at Washington, necessarily attract around them men of eminence in the various branches involved in the proper prosecution of their duties. Professor Henry was elected president of the new society, and the usual officers were also chosen.

THE library of the Smithsonian Institution at Washington now numbers about 70,000 volumes, including pamphlets. In this collection are comprised complete series of the Transactions of many of the older societies of England and France; and many works which it would be almost impossible to obtain except by the system of exchange which the Society has organised with the scientific publications of societies and individuals throughout the civilised world.

THE rapid decrease of food fishes on certain parts of the seacoast and in the lakes of the United States has for a long time been a subject of much solicitude to thoughtful persons: and various causes have been suggested for this state of affairs, and remedies proposed for its correction. Laws have been passed by most of the New England States, and by the British provinces, regulating and protecting the fish and fisheries in the inland waters; but as the jurisdiction of the States does not extend over the high seas, no special effort has been made on their part to protect the marine species by legal enactments. In view of the difficulty referred to, a bill was introduced at the last session of Congress providing for the appointment of a Commissioner of Fish and Fisheries on the part of the United States, to make inquiries as to the alleged facts, and to report upon the same to Congress, together with any suggestions for legislative action in the premises, and the President has just appointed Professor Baird, of the Smithsonian Institution, as the Commissioner in question, with instructions to enter immediately upon the discharge of his duties.

WE regret to learn from a letter from Cairo that Dr. Gedge, the medical man and naturalist of the Viceroy's expedition under Sir S. Baker, fell sick some considerable distance above Khartoum. He was sent back, but did not get farther than Khartoum, where he died of acute mania. Mr. Wood, Sir S. Baker's secretary, was also, on account of sickness, obliged to return, and is now under medical care in Cairo. The last news from Sir S. Baker is to the effect that he is still endeavouring to make a passage through a part of the river that is filled up with dead trees and mud for two or three miles. This is situated about 6° N. lat.

EXAMINATIONS in connection with the Exeter Science Classes will take place at the Albert Memorial Museum on the following dates:—Inorganic Chemistry, May 4th; Animal Physiology, 5th; Machine Construction and Drawing, also Building Construction, 6th; Mathematics, Stage 1, 2, 3, May 8th; Physical Geography, 9th; Acoustics, Light, and Heat, 10th; Navigation and Geology, 11th; Magnetism and Electricity, 12th; Theoretical Mechanics, 16th; Applied Mechanics, 20th; Vegetable Physiology, 18th; Systematic Botany, 12th; Mathematics, Stage 4, 5, May 20th.

AT the recent annual meeting of the American Geographical and Statistical Society, Prof. D. C. Gilman, of Yale College, devoted his annual address to a sketch of the last ten years of geographical work in America. He referred especially to the publication by the Maine Historical Society of an elaborate treatise by Dr. J. G. Kohl on the early voyages to America; the topographical work of the United States' Coast Survey; the new geological maps of New Jersey, by Prof. Cook; the work of Humphreys and Abbot on the Mississippi river; the geological surveys of Ohio, Indiana, and Nebraska, by Profs. Haydn and Newberry; the topographical survey by the North-west Boundary Commission, from the Rocky Mountains to the Pacific Ocean; and the explorations of Colorado with its wonderful canons.

A PROSPECTUS is being sent out of a new work on Fungology:—Mycological Illustrations, being Figures and Descriptions of new and rare Hymenomycetous Fungi; edited by Mr. W. W. Saunders, assisted in the text by Mr. A. W. Bennett, and in the drawings by Mr. W. G. Smith. The first number will be published by Mr. Van Voorst on May 1st.

THE *Meteorological Magazine* for February contains a paper on certain Variations of Temperature during the Solar Eclipse of December 22, 1870, by Mr. Townsend M. Hall, the conclusions of which are as follows:—"The total amount of depression at the time of the greatest obscuration was 21°·75, and I would submit that these figures represent more exactly the influence of an eclipse, than if the observations had been taken at any other period of the year. During the summer months both the atmosphere and the earth are so charged with heat, that a partial darkening over of the sun for so short a time loses, to a certain degree, its effect—the diminution of warmth being partially neutralised, before it can reach the earth, by reason of its passage through the intervening atmosphere. It is to be hoped that similar observations will have been made at some point along the line of total obscuration, whilst, on a future occasion, it will remain an interesting question to be determined by meteorologists, how far the thermal depression varies with the season of the year and the climate of the locality."

WE have received a paper on a Wind-direction Rain-Gauge, by Mr. J. R. Napier, F.R.S. The principle of this gauge consists essentially in supporting a vessel, like the first receiver of an ordinary gauge, on a pivot, so that it may be turned with the least wind, and having a spout attached to it, leading the rain into vessels in fixed directions surrounding the receiver, so that if it rains, for example, when the wind is between N.N.W. and N.N.E., the north vessel receives it, or when between N.N.E. and E.N.E., the north-east vessel receives it, &c.; for there are eight vessels which show the amount of rain and direction of the wind at the time.

THE Geologists' Association has paid visits during the past month to the British Museum and the Museum of Practical Geology; and have arranged for excursions on April 10 to Cambridge to visit the Woodwardian Museum and the exposures of cretaceous strata in the neighbourhood of Barnwell, under the guidance of Mr. Wiltshire and Mr. Bonney; to the Zoological and Hunterian collections of the Royal College of Surgeons April 18; and on April 29 to Belvedere and Crayford, led by Prof. Morris, the chief object of interest being the Mammalian remains of the newer Pliocene deposits.

OF late years many discoveries have been made in regard to the habits and characteristics of the aborigines inhabiting the coasts of North America prior to the time of Columbus by careful examination of the artificial heaps of refuse shells, bones, &c., accumulated in the vicinity of their villages. The published researches of Professor Wyman and others have proved full of interest; and as the subject continues to excite the attention of American archæologists, we doubt not that much now hidden will yet be brought to light. As these deposits are usually on or very near the sea, they are much exposed to the wearing of the waves; indeed, their discovery is usually due to exposure of a section by this influence. For this reason it is of importance that the examinations in question should be prosecuted before the heaps have entirely disappeared, as a large proportion will probably not outlive the next half century. We learn from *Harper's New Monthly* that a careful search on the shores of Kent and Northumberland counties, on the eastern coast of New Brunswick, has shown that, in consequence of the wearing away of the soft sandstone shale of the coast for many rods, all traces of the shell deposits, believed to have once existed in abundance, have now entirely vanished.

ACCORDING to a recent report by Dr. Stimpson upon the Crustaceans dredged in the Gulf Stream by Count Pourtales, of the Coast Survey, eighty-one species, of forty-seven genera, were obtained, of which fifty-two of the species and nineteen of the genera are to be considered as new. Only a small proportion of the species were from great depths, fifteen alone being recorded as coming from below 100 fathoms. The greatest depth at which any of the species were found was 150 fathoms, these belonging to the family of the *Portunidæ*. The portion of Dr. Stimpson's report on the brachyurous crabs of this collection has just been published in the Bulletin of the Museum of Comparative Zoology at Cambridge, already so well known for the merit of its zoological memoirs, and the remainder will follow at no distant interval.

DR. KESSLER claims to have discovered lately in Cassel the oldest herbarium known, some of the plants having been prepared in 1556. It contains 614 plants, properly fastened down and labelled, and was formed by Caspar Katzenberger.

A PLAN has been introduced at the Society of Arts, which has found favour so far, for instituting a kind of British Association for Indian topics under the name of the Oriental Congress of Great Britain and Ireland. It will embrace geology, natural history, biology, and other branches of science, and their economical applications. The proposal to hold the first meeting at Manchester met with the approval of the representatives of the Cotton Supply Association.

THE Colaba Observatory at Bombay recorded in three nights only in January 2·28 inches of rain. This is said to be unprecedented there, and generally throughout the Presidency there has been a fall of rain threatening the cotton crops.

UNDER the title of "Comision de la Flora Forestal Espanola," a useful account is published of the trees most suitable for forest cultivation in Spain, with remarks on the importance of keeping up the forests to maintain the equilibrium of the climate.

AT a time when the small-pox is so prevalent, and vaccination has become, so to speak, fashionable, it is surprising that we do not hear something of the many reputed remedies of foreign countries, either as a cure for this disease or as an eradicator of its effects. The *Sarracenia purpurea* is well known for its supposed efficacy, and it was even introduced into this country some few years back. But a plant not so well known in Europe is the *Melia Azadir-achta* L. of India, the leaves of which are used by the natives to cover the bodies of patients recovering from small-pox, as they are supposed to prevent the mark becoming permanent. Dr. Wright says of this tree that "the leaves beaten into a pulp, and externally applied, act like a charm in removing the most intractable form of Psora and other pustular eruptions."

IN a recent article, *Harper's Weekly* referred to the fact that torpedoes were being used for killing fish for manure on the coast of Florida. This business is being carried on about six miles below New Smyrna, at Mosquito Lagoon; and the method adopted is said to consist in exploding the torpedoes in the water, under the schools, as they pass by. In addition to the many that are killed outright and float on the surface, large numbers are wounded, and go off elsewhere to die without being caught. This practice, we are assured, has already resulted in a very marked diminution of the schools of fish in that vicinity, and has been greatly resented by the people of the State, who are endeavouring to drive the operator from its waters.

AN earthquake at Arequipa in Peru, on the 21st December, was strong, and is said to have lasted fifty or sixty seconds. It was attended with much subterranean noise.

AN earthquake shock was felt at Bombay and as far north as Baroda on the night of January 31. It was distinctly noticed over a large area, but did little or no damage.

RECENT telegraphic advices from Havana announce that Captain Selfridge, who is engaged in prosecuting the Darien ship-canal exploration, thinks he has discovered a practicable oute over a line where the elevation of the divide is not more than three hundred feet above the level of the sea. The despatch is dated Paya, on the Tuira River, a stream which empties into the Gulf of San Miguel, on the Pacific.

THE well-known Pinang or Betel nuts, the seeds of *Areca catechu*, a handsome palm cultivated in all the warmer parts of Asia, and used by the natives to chew with lime for the purpose of producing a gentle kind of intoxication, form an important article in the interior trade of the Malayan Archipelago, being exported from Sumatra to other islands in large quantities. The exports from Padang alone in one year amounted to 5,057 piculs.

FROM the twenty-sixth Report of the Proceedings of the Calcutta School-Book Society, we learn that during the two years 1868-1869, more than 179,300 rupees was spent in purchases of books for distribution among the natives, the object of the society being "to supply and distribute, at the lowest possible price, a healthy household literature in the vernacular tongues," in which it is assisted by a small monthly grant from Government. The titles of some of the works circulated sound to us peculiar, as "A Treatise on Spiritualism and its Manifestations," "A Drama against Upstarts," "The Grief of Females on the Departure of their Husbands by Rail on Monday," &c.; while the modicum of science given is very small; and, judging from the titles, we should suppose that the instruction in natural and physical science, thought good enough for the natives of Hindostan, is about on a par with that which prevailed in this country in the time of Oliver Goldsmith.

THE Berwickshire Naturalists' Field Club, the oldest society of the kind in Britain, has issued its "Proceedings" for 1870. Besides one or two archæological papers, and an address from the President, the Rev. G. S. Thomson, we have the following coutributions to Natural History and Ethnology, chiefly connected with these branches as represented in the district:—"The History of the Wolf in Scotland," "Turnip Insects during 1870," "Botanical Notices," and "Contributions to the Entomology of the Cheviots," chiefly in coleoptera; all these from Mr. James Hardy. The Secretary, Mr. George Tate, contributes a carefully worked-out paper on "The Stature, Bulk, and Colour of the Eyes and Hair of Native Northumbrians;" and Mr. Ralph Carr treats of "The Northumbrians between Tyne and Tweed." There are several other short papers of local interest, and a statement of the rainfall concludes the number.

IN a discussion at the Indian Conferences at the Society of Arts, as to a proposition of Col. Wragge to employ Neilghery peat on railways, it was mentioned that the two largest peat bogs near Ootacamund have been swept away in rains. This was alleged to be through cutting them at the wrong end.

WE learn from Nicaragua that the river and port of San Juan del Norte are shoaling in many places. Where there was deep water in the latter ten years ago, there is now a bank above the surface.

ON THE CONNECTION BETWEEN TERRESTRIAL TEMPERATURE AND SUN-SPOT PHENOMENA

MR. STONE, the newly-appointed Astronomer Royal at the Cape of Good Hope, has recently communicated to the Royal Society an important paper and curve, in which the thermometric observations taken there since 1841 are discussed. This curve he has compared with another constructed on Wolf's observations of sun-spots, and with the following result, which we give in his own words:—

"The agreement between the curves appears to me so close that I cannot but believe that the same cause which leads to an excess of mean annual temperature leads equally to a dissipation of solar spots. There is on the whole a curious appearance of logging of the inverse curve of solar spots over that of temperature. At the maximum about 1856, this, however, does not appear to be the case; but when the uncertainties of the data, both of the solar spots near the minimum, and of the mean temperature also, are taken into account, such discrepancies might perhaps fairly be expected, even if there be a physical connection between the two phenomena as results of some common cause. If there be a sensible inequality in the mean temperature with a period of about ten years, then the mean temperature resulting from the observations in the temporary observatory, which were made near a maximum, will be too high. The corresponding ordinates, therefore, will be depressed too much relatively to those corresponding to observations made in the other two observatories. In the curve 2 I have imperfectly corrected the mean of the results for the temporary observatory on the supposition of such an inequality existing. The only result of such a correction is to modify the curve at the points of junction of the observations made in different positions. The general form is unaltered. It should be mentioned that the point about which the curves appear to differ most is near or at the change of exposure from the original observatory to the temporary shed about 1852.

"I may mention that I had not the slightest expectation, on first laying down the curves, of any sensible agreement resulting, but that I now consider the agreement too close to be a matter of chance. I should, however, rather lean to the opinion that the connection between the variation of mean temperature and the appearance of solar spots is indirect rather than direct, that each results from some general change of solar energy. . . . . The problems of meteorology appear to be presented here in a simpler form than in England, and probably systematic photographic self-registering observations extended over a few years might lead to important results."

EXPERIMENTS ON CERTAIN VIBRATORY PHENOMENA

THE apparatus made use of consists simply of a cardboard disc furnished with radial slits, and which can be rotated with any desired velocity. To examine a coal-gas flame singing in a glass tube, the disc is placed in front of the flame, and the eye placed where the slits pass in a vertical position. When the dish rotates with such a velocity that the interval between two slits passing the eye is just equal to the period of a complete vibration of the flame, the flame appears to be motionless; but if the velocity of the disc be slightly reduced, the flame is seen slowly to go through its changes of form, appearing to consist of a series of puffs, resembling those from the funnel of a luggage locomotive. When the interval between the passing of the slits is equal to, or is one-half, one-third, &c., of the period of vibration of the flame, a singular appearance of a phantom disc is seen, having as many or twice or three times the number of slits really in the disc; this phantom wheel appears motionless if the periods exactly coincide, but if they do not, it slowly revolves in one direction or the other. It is obvious that this affords an easy method of counting the vibrations of the flame. With a sixteen inch tube I thus found the number of complete vibrations per second to be about 453.

When the disc is rotated in front of a vertical vibrating wire, the eye being placed where the slits pass in a horizontal position, the interval of the slits passing being equal to a complete vibration of the wire, the wire appears thrown into undulations and motionless. If the periods do not exactly coincide, the undulations travel up or down the wire. If the velocity of the disc be doubled, or trebled, the apparent number of wires is increased in like proportion; and if it be regarded by the two eyes placed where the slits do not pass in a horizontal position, they assume the form of spirals, which appear to revolve around each other in an extremely beautiful and illusive manner. In the above cases I have supposed the wire to be twanged in the centre, in which case the undulations are beautifully symmetrical curves, and represent a pure note. If, however, the wire be twanged near to one end, the change in the *quality* of the note is manifest, the irregularity of the curves showing the presence of minor undulations superimposed upon the primary one. The best wire for this purpose is a fine spiral one, as it gives vibrations of great amplitude, and of long continuance. A vibrating steel rod also appears thrown into the same undulations.

CHARLES J. WATSON

THE ACTION OF FLUORSPAR ON DIFFERENT QUALITIES OF CAST IRON

IN my articles contributed to NATURE (No. 57, p. 94, and No. 61, p. 233), I have given descriptions of my process of applying fluorspar combined with oxides, and fluorspar combined with oxides containing titanium, to ordinary cast iron.

It is reported that attempts have been made to apply fluorspar alone to ordinary cast iron by eminent chemists in the laboratory, but the results have been of a negative character. These reports have been corroborated by my own experiments. I have discovered,* however, that although fluorspar has no effect when used alone in treating ordinary cast iron, it will act energetically upon cast iron containing titanium. The titaniferous cast iron was made at Glassdale Furnaces, near Whitby, by melting Cleveland white pig iron in a cupola in admixture with Norwegian titanic iron ore, and blast furnace cinder as a flux. This metal was treated here in the laboratory by being melted upon powdered fluorspar. The resulting metal was found to be wrought iron.

These results may be obtained in any suitable vessel, furnace, apparatus, or process; the only conditions necessary to be observed are, that the metal be maintained in the fluid state, and the fluorspar placed so as to act upon the metal from the under side upwards, or placed in admixture with it, and that when apparatus is used having silicious linings, the silicious linings be protected with sheet or cast iron placed upon the silicious lining before the fluorspar and iron to be treated are charged into the vessels. No labour is necessary, except that of "balling" the metal, and removing it from the apparatus.

The results given by this experiment go to prove that by this process superior qualities of wrought iron, which will be purer than the highest standard brands of wrought iron, may be produced from the English Cleveland pig iron, which contains, according to the best metallurgical authorities, from 1·25 to 1·38 per cent. of phosphorus.

One ton of Cleveland pig iron was melted in a cupola with 7 cwts. of Norwegian titanic iron ore, containing, by analysis, about 40 per cent. of titanic acid. The resulting metal was titaniferous cast iron, analysing :—

Titanium	1·2551
Silicon	1·8139
Phosphorus	0·4604
Sulphur.	0·3620
Carbon	1·2982

* Patent No. 318, Feb. 3, 1870

Hence it appears that the iron, by being re-melted with titaniferous iron ore, took up 1·25 per cent. of titanium, and lost 0·90 per cent. of phosphorus, and 1·75 per cent. of carbon. It is obvious that the metal in this condition is not available for any purpose without subsequent treatment, as it contains about as great an amount of impurities as it did before treatment.

The advantages gained by re-melting the pig iron with titaniferous iron ore are, a reduction of the amount of phosphorus and carbon, and the alloying of the metal with titanium, which facilitates the removal of the impurities in the subsequent treatment.

The above described titaniferous cast iron was remelted upon fluorspar, and about 30 minutes after the iron melted, or in about an hour after they were both charged, the iron was found to be malleable iron; the button analysing as follows :—

Titanium	0·0215
Silicon	None
Phosphorus	0·1399
Sulphur.	0·0620
Carbon	Traces

When worked on a larger scale, so as to produce blooms that can be worked into merchantable shapes, the finished results will show less phosphorus and sulphur than the above analysis, as it is well known to metallurgists, by the experiments of Messrs. Calvert and Johnson, published in full in Kerl's "Metallurgy," vol. ii., "Copper and Iron," 1869, that 0·022 per cent. of phosphorus, and 0·040 per cent. of sulphur, are removed in working blooms into finished iron.

It will be seen that the action of the fluorspar removed 4·9662 per cent. of the impurities contained; and that the resulting metal contains less impurities in amount than the highest standard qualities of wrought iron. The explanation of these effects I leave to chemical investigators, without hazarding an opinion which might be erroneous, and therefore disadvantageous to me.

JAMES HENDERSON

MR. WALLACE'S ANNIVERSARY ADDRESS*

A CONSIDERABLE portion of this Address is devoted to a discussion of the facts of distribution of beetles, as presented by Mr. Wollaston in his great work, the "Insecta Maderensia," with special reference to the views advocated by Mr. Andrew Murray, in his paper on the Geographical Distribution of Beetles. After touching on the various methods by which insects are known to be distributed, and mentioning several of the instances in which they have been captured some hundreds of miles from land, it is concluded that, in opposition to the view held by Mr. Murray, there is no reason to believe that the Atlantic islands owe their Coleoptera to a former land connection with the continent, more especially as there is such strong evidence against that view in the total absence of mammals and reptiles. Mr. Wallace then applies Mr. Wollaston's facts to a detailed test of these views; and, as this portion of the paper is of general interest to naturalists, we give it at length :—

The most novel and striking facts brought out by Mr. Wollaston's researches in Madeira are, as is well known (1) the affinity with the Mediterranean fauna; (2) the total absence of certain large divisions of Coleoptera abundant in that fauna; (3) the number of new and peculiar species and of new and anomalous genera; and (4) the unexampled preponderance of apterous species. Now accepting, as Mr. Murray does, the theory of slow change of forms by natural causes, we may take the first and third of these facts as proving that the origin of the Madeiran fauna is of very ancient date. Let us see, therefore, how the second and the fourth set of facts bear upon the mode of its origin, whether by a land-connection with Europe or by transmission across the sea. It will be convenient to take first the facts presented by the apterous or winged condition of the species.

This striking peculiarity consists, either in species being apterous in Madeira which are winged elsewhere, or in genera which are usually winged consisting of only apterous species in Madeira, or lastly, in the presence of endemic apterous genera, some of which have winged allies, while others belong to groups

* An Address read at the Anniversary Meeting of the Entomological Society of London, on the 23rd of January, 1871, by Alfred R. Wallace, F.Z.S., F.R.G.S., President.

which are wholly apterous. Such phenomena undoubtedly show that there is something in Madeira which tends to abort wings; and Mr. Wollaston was himself the first to suggest that it was connected with exposure to a stormy atmosphere. His further observation, that many of the winged species had wings more developed than usual, enabled Mr. Darwin to hit upon that beautiful explanation of the facts which commends itself to all who believe in the theory of Natural Selection, while Mr. Wollaston himself admits it as fully accounting, teleologically, for the phenomena. That explanation briefly is, that the act of flying exposes insects to be blown out to sea and destroyed; those which flew least therefore lived longest, and by this process the race became apterous. With species to whom flight was a necessity, on the other hand, the strongest-winged lived longest, and thus their wings became more and more developed in each succeeding generation.

Now this view of the case enables us at once to explain some of the most striking gaps in the Madeiran coleopterous fauna. The Cicindelidæ, for instance, are entirely absent; and almost all the European species are winged insects of somewhat feeble flight, yet to whom flight is necessary. We can readily understand that such insects would be easily exterminated if they arrived singly or in small numbers; though it is not so easy to understand why, in a forest-clad island, some of the sylvan species should not have found a home had the land ever been connected with a continent where they abound. Their total absence is, therefore, decidedly unfavourable to the theory of a land-connection with Europe. To the Melolonthidæ and Cetoniidæ, as well as the Eumolpidæ and Galerucidæ, which are all wanting, the same argument will apply; and also to the Elateridæ and Buprestidæ, which are represented each by one minute species. But if Madeira is the remains of a continent once continuous with the south of Europe and deriving its fauna from such continuity, how are we to explain the absence of extensive genera very abundant in South Europe, and, from their being apterous, specially adapted to the peculiarities of Madeira? Such are *Carabus*, *Lampyris*, *Pimelia*, *Akis*, and many others. But these facts are all consistent with the theory of introduction across the sea. Apterous groups, however abundant on the continent, should, as a rule, be absent; and I find that almost all the European apterous genera are wanting, and among the few exceptions there are some whose presence is easily explained and really prove the rule. We must remember, however, that the apterous condition, except in those cases where it is characteristic of an extensive group, is one of little stability or importance. There are species which are sometimes apterous and sometimes winged, and we may therefore be sure, that if any advantage was to be derived by either condition over the other, Natural Selection would very rapidly render it constant by the repeated survival of the favoured individuals. This is illustrated by the fact that we have winged and apterous species in the same genus, as well as winged and apterous genera in the same family. The coleopterous order being essentially winged, and the vast majority of its members being capable of flight, it is a presumption, if not almost a certainty, that all apterous varieties, species, or groups, have been derived from winged ancestors—comparatively recently in the case of the former, and at a more remote epoch as the character becomes more constant and attached to groups of higher classificational value.

Taking these principles as our guide, let us examine more closely the facts presented by the Madeiran Coleoptera, and their bearing on the rival theories as to their mode of introduction.

There are a large number of European beetles belonging to the very varied genera and families which are apterous, and a large proportion of these inhabit the south of Europe and North Africa. Now, on the theory of land connection, there should be no marked absence of these groups; on the contrary, apterous forms being especially adapted to Madeira, we should expect them to predominate. But, on the opposing theory of transmission across the sea, we should expect them to be wholly absent, or, if there are any exceptions, we should expect to be able to detect some special circumstances which might favour their transmission. A careful examination of Lacordaire's "Genera," and of some works on European Coleoptera, has furnished me with the following list of genera which are wholly apterous, and which abound in South Europe and North Africa.

Carabus possesses about eighty species in these regions; but is wholly absent from Madeira.

Thorictus has ten South European species, and one representative in Madeira, which is an ants'-nest species.

Rhizotrogus (Melolonthidæ), twenty-seven species in Sicily and Algeria, the very country to which the Madeiran fauna is traced, yet it is wholly absent.

Lampyris, *Drilus*, and *Troglops* (Malacoderms), of which the females are apterous, possess twenty-seven South European and North African species; none in Madeira.

Otiorhynchus, *Brachycerus*, and twenty other genera of Curculionidæ, comprising more than 300 South European and North African species, are absent from Madeira, with two exceptions. One is the *Trachyphlœus scaber*, a widely-spread European insect often found in ants' nests; and this, with the case of the *Thorictus*, renders it probable that ants'-nest species have some unusual means of distribution, which are by no means difficult to conceive. The other exception is that of the genus *Acalles*, which has a number of Madeiran species, all peculiar, and is very abundant in all the Atlantic islands. Now we have first to remark that *Acalles* is an isolated form, but is allied to *Cryptorhynchus*, which is often amply winged; so that we may easily suppose that its introduction to Madeira took place before it became completely apterous in Europe. In the second place we have the fact, that many of the species are confined to peculiar herbaceous and shrubby plants, in the stems of which they undergo their transformations, and which habit would afford facilities for their occasional transmission in the egg or pupa state across a considerable width of ocean, while a fragment of dry stem containing egg or larva might possibly be carried some hundred miles or more by a hurricane. Such suppositions would not be admissible to account for numerous cases of transmission, but, as will be seen, this is almost the only example of a genus of large-sized apterous European beetles occurring in Madeira.

Pimelia, *Tentyria*, *Blaps*, and eighteen other genera of Heteromera, comprising about 550 species of South Europe and North Africa, are totally absent from Madeira, with the following interesting exceptions:—two common species of *Blaps*, which are admitted to have been introduced by human agency, and three species of *Meloe*, two of which are European and one peculiar. The means by which the apterous, sluggish, and bulky Meloes were introduced is sufficiently clear, when we remember that the minute active larvæ attach themselves to bees, insects of exceedingly powerful flight, and more likely than perhaps any other to pass safely across 300 miles of ocean. That the solitary exception to the absence of wholly apterous genera of European Heteromera from Madeira should be the genus *Meloe*, is, therefore, one of those critical facts which almost demonstrate that it is not to land-continuity with the continent that the island owes its insect fauna.

Timarcha.—This, the only important apterous genus of Chrysomelidæ, is especially abundant in Spain and Algeria, and possesses forty-four South European and North African species; yet it is unknown in Madeira.

The occurrence of two isolated European species of characteristic Atlantic apterous genera—Tarphius and Hegeter—may seem to favour the opposite theory. The *Tarphius gibbulus* occurs in Sicily, and is the only European species of the genus of which about forty inhabit the Atlantic islands. It is most nearly allied to the smallest of the Madeiran species, *T. Lowei*, which is abundant among lichen on weather-beathen rocks, and even ascends in the forest regions to the highest branches of the trees. These habits, with its minute size, are all in favour of this species, or some ancestral allied form, having been carried across by the winds or waves, thus transferring to Europe one of the peculiar types elaborated in the Atlantic isles. The *Hegister tristis* is an analagous case, this species of an otherwise exclusively Atlantic genus having occured on the opposite coast of Africa. These instances will furnish a reply to one of Mr. Murray's difficulties,—that all the migration has been in one direction, from Europe to Madeira, never from Madeira to the continent,—a difficulty, it may be remarked, which is wholly founded on an unproved and unprovable assumption; for how can it be determined that, in the case of *Acalles* for example, the genus had not been first developed in the Atlantic islands and then transferred to Europe, instead of the reverse? It is always assumed to have been the other way, but I am not aware that any proof can be obtained that it was so, and it is inadmissible to take this unproved assumption, and base an argument upon it as if it were an established fact.

We will next consider the facts presented by the distribution of those species of Coleoptera which range from Madeira to Europe, or to any of the other Atlantic islands. If their distribution has been effected by land-continuity, we should expect that the proportion of winged and apterous species that extend their range beyond the island, should not be very strikingly different from the proportion that is found on the island. We do not find, for example, that the proportion of the win.less *Carabi* that have reached our own country from the continent by former land connection, is very different from that of the winged *Cicindelæ*.

Now, leaving out altogether those species which have certainly been introduced by man, and grouping the remainder for convenience in six divisions, we find that the Madeiran Coleoptera, which are not peculiar to it, may be classed as follows :—

31 species of Carabidæ, of which 26 are winged, 5 apterous. The whole fauna, however, presents the very different proportion of 38 winged, 43 apterous.

93 species of the families from the Hydradephaga to the Tomicidæ inclusive, of which 90 are winged, 3 apterous. Total fauna ; 220 winged, 27 apterous.

28 species of Curculionidæ, of which 26 are winged, 2 apterous. Total fauna ; 35 winged, 74 apterous.

15 species of Longicornia and Phytophaga, of which 15 are winged, none apterous. Total fauna : 48 winged, 1 apterous.

20 species of Heteromera, of which 16 are winged, 4 apterous. Total fauna : 28 winged, 27 apterous.

76 species of Staphylinidæ, of which all are winged, none apterous. Total fauna : 109 winged, 6 apterous.

The totals are, for the wide-ranging species, 249 winged, 14 apterous = 263 ; for the whole fauna, 478 winged, 178 apterous = 656.

It thus appears that, in every case, an immensely smaller proportion of apterous than of winged species are widely distributed. If we take the totals, we find that while about two-fifths of the whole number of species range to other countries, only about one-thirteenth of the apterous species do the same, although among the strictly endemic species there are 160 apterous to only 110 winged ! We can hardly impute such a constant and overwhelming preponderance to the fact that apterous insects have less facilities for extending their range, when we know that nearly every apterous genus possesses species of almost universal European distribution. I may here recall the fact, that of the above-mentioned fourteen apterous species which range out of Madeira, two are Meloes and two ants'-nest beetles, whose presence we have already sufficiently accounted for. It may no doubt be said that much of the difference here shown is due to the fact that the peculiar Madeiran species have had time to become apterous, while the species common to other countries have not yet had time to lose their wings ; but this argument, although a valid explanation of some portion of the facts, if we admit that many of the latter have been *recently introduced by natural causes*, cannot be used by those who maintain a former land-connection as the sole origin of the fauna ; for on that theory all the species now inhabiting the island (and not introduced by man) must date back to the same remote period, and have had equal time in which to be modified.

Let us now consider what are the special relations of the apterous Madeiran species as throwing light upon their possible or probable mode of introduction.

We have three species which Mr. Wollaston himself states to be usually winged elsewhere, but which are apterous in Madeira. These are *Metabletus obscuroguttatus*, *Calathus fuscus*, and *Bradycellus fulvus*. I am inclined to believe that there are a few others which will come under this category, but it is very difficult to get information as to the winged or apterous character of particular species. These insects, however, have evidently become apterous since their introduction into Madeira. We have therefore no difficulty in accounting for their introduction, and, as no other change in their external characters has been effected, we may suppose it to have been comparatively recent.

Next we have those genera which, though apterous in Madeira, are wholly or partially winged elsewhere. These comprise a large number of species, and are twenty-two in number, as follows :— Carabidæ : *Cymindis, Dromius, Metabletus, Scarites, Apotomus, Loricera, Leistus, Calathus, Olisthopus, Argutor, Cratognathus, Bradycellus, Trechus.* Philhydrida : *Hydrobius.* Byrrhidæ : *Syncalypta.* Curculionidæ : *Phlœophagus, Tychius, Smicronyx.* Heteromera : *Phaleria, Helops.* Staphylinidæ : *Homalota* (1 sp.), *Othius.* Here we are carried back to a remoter epoch for the introduction of the winged ancestors of the Madeiran species, since not only have the wings become aborted, but the insects themselves have become modified into distinct and often very well marked species.

The next category consists of apterous genera which are peculiar to Madeira and the other Atlantic islands, but which are allied to winged groups, as follows :—

Elliptosoma.—Closely allied to *Loricera*, winged.

Eurygnathus.—An abnormal form of Licinides, most of which are winged.

Zargus.—An abnormal form of Chlæniides, winged.

Thalassophilus.—Allied to *Trechus*, winged.

Tarphius.—Belonging to the Colydiidæ, most of which, Mr. Pascoe informs me, have wings.

Coptostethus.—Allied to *Cryptohypnus*, winged.

Caulophilus.—Allied to *Phlœophagus*, winged.

Lipommata, Mesoxenus, Caulotrupis.—Anomalous genera of Cossonides, which are often winged.

Acalles, Torneuma.—Aberrant genera of Cryptorhynchides, most of which are winged.

Echinosoma.—Doubtful affinities.

Atlantis, Cyphoscelis, Laparocerus (Laparocerides).—A very isolated group.

Anemophilus, Scoliocerus.—Allied to Trachyphlœides, some of which are winged.

Lichenophagus.—Allied to *Cœnoposis* and *Omias*, some of which are winged.

Xenorchestes.—Allied to *Choragus*, winged.

Ellipsodes.—Closely allied to *Crypticus*, some of which are winged.

Hadrus.—Belongs to an apterous group of Opatrides, many of which are winged.

Macrostethus.—Belongs to Cœlometopides, all of which are apterous, but comes next to the *Tenebrionides vrais*, of Lacordaire, which are mostly winged.

Xenomma.—Belongs to the Aleocharides, which are winged.

Mecognathus.—Allied to *Sunius*, winged.

Metopsia.—Allied to *Phlœobium*, winged.

Here we have indications of an introduction of forms at a still more remote epoch. In many cases the modifications of structure have been so great as to produce distinct generic forms, while these remain still allied to winged European genera. In other cases, however, the modifications are still greater, and the affinities are with groups which in Europe are wholly apterous. Such cases as *Hadrus* and *Macrostethus*, which belong to small groups of wholly apterous genera, are difficulties on the theory of transmission over the sea. But two considerations render this difficulty less real than apparent. They all carry us back to a very remote epoch ; and, knowing what we do of the instability of the apterous condition, we may fairly conclude that the groups in question were, at that time, in a partially winged state. At or near this same remote epoch, the Madeiran group, as indicated by the submarine bank now connecting the several islands, probably formed one more extensive island, and the distance of ocean to be traversed would then have been considerably less than it is now.

If the various groups of facts which I have here set forth, respecting the distribution of apterous and winged species and genera, are fairly considered as a whole, I think they will be seen to be quite inconsistent with the theory of that distribution having been effected by a former land connection with Europe ; and, considering that we are necessarily ignorant of many of the ways by which organisms are transmitted across ocean barriers, such transmission seems to be indicated in the case of the Madeiran Coleoptera, not by means of drift wood and ocean currents, which Mr. Murray thinks must be the most efficient means of transport, but by some mode in which their wings are called into play, which can only be by a passage through the air when assisted by gales and hurricanes.

There is one other group of islands which seems well adapted to offer a crucial test of the correctness of the theory of land-connection. The Azores are more than twice as far from Europe as the Madeiras, and, what is of still more importance, they are cut off from it as well as from the Madeiras by a broad belt of ocean of the enormous depth of nearly 15,000 feet. We may feel pretty confident, therefore, that if both groups have once been united to the continent, the separation of the Azores is by far the more ancient event ; and any theory which requires the Azores to be the most recently separated must be strongly supported by independent evidence to render such an improbable supposition acceptable. If the Azores date the origin of their insect population from a remote epoch when they were connected with

Europe, we should expect to find that almost all the species have since become modified, and that these islands would offer us a larger proportion of highly specialised and ultra-indigenous forms than Madeira itself. The exact contrary, however, is the fact, for, out of more than 200 species only about sixteen are peculiar.

Taking the geodephagous group, the species of which, both Mr. Murray and Mr. Wollaston believe, are least liable to be introduced by man, we find that two only are peculiar, while sixteen are European. The Rhynchophora only equal the Geodephaga in number of species, and seven of these are peculiar. Leaving out a large number of species which have, there is little doubt, been introduced through human agency, there remain more than 100 species identical with those of Europe and the Atlantic islands, while only fourteen are peculiar. These facts imply that the insects, as a whole, have been brought to the islands through natural causes, and that the process is probably still going on. On looking to Physical Maps for information, however, a difficulty appears; for the ocean currents, as well as the prevalent regular winds, are all from the westward, while only four of the beetles are American, and these being all woodborers, have no doubt been brought by the Gulf Stream where they have not been introduced by man. Fortunately, however, we have a means of getting over this difficulty; for our member, Mr. F. Du Cane Godman, who has given us the most recent and accurate information on the natural history of these islands, informs us (in his paper on the birds of the Azores in the "Ibis" for 1866) that the stormy atmosphere, to which we have seen that Madeira owes so many of its peculiarities, is still more marked a feature of the Azores, where violent storms from all points of the compass are frequent, and annually bring to their shores numbers of European birds. As a natural result of this constant influx, the birds of the islands are, all but two, of European species; and, what is very important, they decrease in numbers from the eastern to the western islands of the group. This is just what we should expect if they are stragglers from the eastern continent; but if they are the descendants of those which inhabited the country before its dismemberment, there would be no meaning in such a diminution. Now we can hardly doubt that these same storms also bring Coleoptera and other insects to the Azores, though it may be more rarely and in smaller numbers than in the case of the birds; and the large proportion of European species will then be very intelligible. The same explanation is suggested by the proportions of the most important groups, for while (after deducting all those species believed to have been introduced by man) the Geodephaga and Brachelytra are by far the most numerous, the Rhynchophora and the Heteromera are exceedingly few, a distribution which corresponds with their respective powers of flight. It is also a very important fact that only four non-introduced species can be traced to an American origin, while more than a hundred are European; since it shows of how little importance are ocean currents as a means of conveying insects over a wide extent of sea; whereas the great mass of the non-introduced species have evidently passed through the air, aided by their powers of flight, for a distance of about a thousand miles from Europe. The Azorean Elateridæ form a curious feature of its fauna, considering that the whole family is almost absent from Madeira and the Canaries. Of the six species two are European (one specially Portuguese), so that they may have been introduced with living plants. Two are common South American species, probably introduced in the floating timber, though they may also have come with living plants, which are often brought from Bahia. Two species, however, are peculiar, and one is closely allied to a Brazilian species, so that it must have been introduced by natural agencies before the settlement of the island; the other is of a genus confined to Madagascar.

Now it is a suggestive fact that the Mozambique current, bending round the Cape of Good Hope to the Equator, is one of the sources of the Gulf Stream; so that it is not impossible that a tree, carried down by a flooded river on the west coast of Madagascar, might ultimately reach the Azores. That it should convey living larvæ or pupæ of Elaters may also not be impossible; and if such a log reached the Azores but once in ten thousand years, and but one log in a thousand should convey living Elaters, we should still, if the calculations of geologists have any approximate value whatever, be far within the epoch of existing genera, and even of most existing species. A relation so isolated and extraordinary as that between a single insect of the Azores and those of Madagascar, may well be due to a concurrence of events as rare and improbable as this seems to be.

The Azores, and in a less degree the Madeiras, appear to me to teach us this important lesson in the laws of distribution of birds and insects—that it has been determined neither by the direction of ocean currents nor by that of the most prevalent winds, but almost wholly by such more exceptional causes as storms and hurricanes, which still continue to bring immigrants from the nearest lands.

SOCIETIES AND ACADEMIES

LONDON

Zoological Society, March 21.—Mr. R. Hudson, F.R.S., in the chair. The Secretary read a report on the additions to the Society's Menagerie during the month of February, 1871.—Mr. Sclater exhibited a skin of the Ceylonese *Prinia*, recently spoken of by Mr. W. Vincent Legge in a communication to the Society, and now forwarded by that gentleman, which appeared to be identical with *P. socialis* of continental India.—An eleventh letter was read from Mr. W. H. Hudson, on the ornithology of Buenos Ayres.—Dr. Hamilton communicated an extract from a letter received from China relating to the reproduction of a Chinese Deer, *Hydropotes inermis*.—Mr. Sclater read a paper on the Birds of Santa Lucia, West Indies, containing an account of a collection recently made in that island by the Rev. Mr. Semper, and forwarded to Mr. Sclater by Mr. G. W. des Vœux. Amongst these specimens were two examples of an *Icterus*, believed to be undescribed and proposed to be called *I. laudabilis*.—Dr. R. O. Cunningham read a paper on some points in the anatomy of the "Steamer Duck," *Micropterus cinereus*, based upon specimens of this bird obtained by him during his recent voyage as Naturalist to the Survey of the Straits of Magellan. A communication was read from Mr. R. Swinhoe, containing a revised catalogue of the Birds of China and its islands. To this were added descriptions of new species, together with references to former notes and occasional remarks.

Chemical Society, March 16.—Prof. Williamson, F.R.S., president, in the chair. Mr. C. H. Piesse was elected a fellow. Mr. C. H. Gill read a note "On the examination of Glucose containing Sugars." It is known that coloured sugar solutions are decolourised and clarified by the addition of basic lead acetate before they are submitted to optical examination. Mr. Gill now found that the power of invert sugar to rotate a ray of polarised light is greatly altered by the presence of that reagent. The alteration takes place only on the levulose in the liquid, the dextrose suffers no change of optical properties. This alteration is not permanent—on removing the lead or acidifying the liquid the original rotatory power is restored. Mr. Gill employs these latter reactions in order to obtain correct numbers with the saccharometer. He uses a strong solution of sulphuric dioxide, which removes the lead, and at the same time bleaches the liquid, but is incapable of inverting cane sugar in the cold even in twenty-four hours. The presence of the lead salt in sugar solutions is also disadvantageous when the glucose has to be estimated by Fehling's copper solution, as it partly becomes reduced, and thus necessitates the use of a greater volume of the saccharine solution; the removal of the lead does away with this source of error.—Mr. D. Howard made some remarks on the boiling point of a mixture of amylic alcohol and water.—Mr. Perkin stated that he had succeeded in obtaining bromacetic acid by gradual addition of bromine to heated acetic anhydride, boiling for some time, mixing with water and subsequent distillation.—Mr. Warrington spoke briefly of an easy and sufficiently correct determination of ammonic sulphocyanide in commercial sulphate of ammonia.

Entomological Society, March 20.—Mr. A. R. Wallace, president, in the chair. Prof. P. M. Duncan, F.R.S., and Mr. E. S. Charlton were elected members. The Rev. L. Jenyns, in a letter to Mr. Dunning, made some remarks on the statement of Mr. Bond, at the last November meeting, respecting the swarming of *Chlorops lineata* in the Provost's Lodge at King's College, Cambridge. Mr. Jenyns had a similar swarm in 1831, and occurring probably in the same room.—Mr. Verral exhibited a fly, *Pipiza noctiluca*, from Perthshire, to the head of which a substance was adhering, probably the pollen-mass of an orchid.—Mr. Müller exhibited a gall, in shape like a grain of wheat, on the leaves of a *Carex*, sent to him by Lord Walsingham from Thetford.—Mr. C. O. Waterhouse read a description of *Apterocyclus honolulensis*, a new genus and species of Lucanidæ from the Sandwich Islands.—Mr. Wollaston communicated a paper on additions to the Atlantic *Coleoptera*, in which he recorded the results of recent observations, with corrections on synonymy, &c. He adhered to his original opinion that the Atlantic archipelagos were the remnants of a former continent, with a possible connection with south-western Europe, and, in this respect, he differed from the views of Mr. Wallace that the islands had received their insect fauna by means of atmospheric agencies, thus agreeing more with the theory enunciated by Mr. Andrew Murray in his recent essay on the geographical distribution of *Coleoptera*. A discussion ensued in which the President, Mr. Bates, and Mr. Murray took part; the two first-named gentlemen considering that the remarkable absence in the islands of reptiles and mammals, was an insuperable objection to the idea of a former Atlantic continent; Mr. Murray, on the contrary, contended that the great homogeneity exhibited in the fauna and flora could only be explained by supposing the islands to have once been connected by a land passage.

Biblical Archæological Society.—The inaugural meeting, which was largely and influentially attended, was held on Tuesday, March 21, at 8.30 P.M. Dr. Birch of the British Museum took the chair, supported by Prof. Donaldson, Captain Wilson, and Messrs. Bonomi, Boyle, Drach, &c. After the usual preliminary business had been transacted the chairman delivered an opening address, enumerating the circumstances which had led to the formation of the Society, and stating the various advantages offered to the scientific world by its institution. A concise summary was then given of the results of past and pending archæological investigations in Assyria, Egypt, Palestine, and Western Asia; these results it was now proposed to extend and systematise by the labours of the Society of Biblical Archæology, while the council hoped eventually to be able to undertake excavations of their own among the still unopened tumuli of Mesopotamia. Prof. Donaldson moved that the inaugural address be printed, and made some excellent remarks upon the necessity of exercising great tact in further investigations, as well as great promptitude in securing such valuable antiquities as were likely to be destroyed by superstitious barbarians.—Mr. Boyle, of Lincoln's Inn, seconded the resolution.—Captain Wilson, in proposing a vote of thanks to the chairman, expressed his pleasure in belonging to two societies, whose labours, though in different spheres, would mutually and materially assist each other.—Mr. S. M. Drach moved that the name of the indefatigable secretary, Mr. W. R. Cooper, should be added in the vote of thanks, seconded by the Rev. T. Gorman, and carried unanimously.—Mr. Bonomi, Rev. A. Mozley, and other gentlemen also addressed the meeting.—A list of papers to be read at future meetings, contributed by Sir Henry Rawlinson, Mr. H. Fox Talbot, Dr. Birch, and Messrs. G. Smith, Bonomi, and Lowne, was then announced, and the society adjourned to Tuesday, 4th April, 1871.

CAMBRIDGE

Philosophical Society, March 13.—"On the Attraction of an infinitely thin shell bounded by two similar and similarly situated concentric ellipsoids on an external point," by Prof. Adams, F.R.S.—"On the theory of the forms of floating leaves in certain plants," by Mr. Hiern, St. John's College. This problem was treated mathematically, the leaf being considered as at its edge a flexible body, acted upon by an outward radial force, that of growth, and an external pressure due to the velocity of the stream. The curves which would be assumed under various conditions were calculated, and shown to agree closely with the forms which are to be found in certain aquatic plants.—"On the effect of exhaustion and inflation of the tympanum in deadening sounds, and on the test of loudness," by Mr. Moon, Queen's College.

MANCHESTER

Literary and Philosophical Society, March 7.—Mr. E. W. Binney, F.R.S., president, in the chair.—"The Action of Sulphurous Acid on Phosphates," by Dr. Wilhelm Gerland, Macclesfield.—"Further observations on the Strength of Garden Nails," by Dr. J. P. Joule, F.R.S. The author thought it desirable to ascertain how far hardness had to do with the strength and elasticity of these small specimens of cast iron. For this purpose he plunged some of them at a heat near the melting point into water, then selecting those which had been hardened sufficiently to resist the action of the file. Others he cooled slowly from a bright red heat. The experiments were conducted in the manner described in the last number of the Proceedings:—

	No. of Experiment.	Length of Nail between Supports.	Breadth of Nail at Fracture.	Depth of Nail at Fracture.	Deflection.	Breaking Weight. lbs.
Hard Nails.	1	1·0	0·11	0·122	·0067	129
	2	1·04	0·12	0·12	·0037	84
	3	1·0	0·12	0·122	·0028	81
	4	1·02	0·143	0·102	·0077	129
	5	1·1	0·138	0·13	·0071	203
	Average	1·032	0·1262	0·1192	·0056	125·2
Soft Nails.	6	1·0	0·112	0·117	·0088	141
	7	1·05	0·139	0·114	·0087	150
	8	1·02	0·130	0·138	·0051	176
	9	1·04	0·117	0·090	·0101	101
	10	1·04	0·121	0·108	·0073	113
	Average	1·03	0·1238	0·1134	·008	136·2

Reducing to a length of 3ft. and 1in. square section, and making a deduction of one-eighth from the deflections, on account of the taper of the nails, the above results, along with those in the last number of Proceedings, become

	Breaking Weight.	Deflection.
Nails in original state .	2673	·922
Hardened ditto . .	2002	·677
Softened ditto . .	2448	·924

—Dr. Joule exhibited three photographs of the sun taken on the 1st December, 1858. The images, ·43in. diameter, were produced by the achromatic object-glass of a telescope with half-inch stop. Exposure, by means of an apparatus completely detached from the camera, during a small fraction of a second. He had been induced to examine them after seeing the beautiful photograph of the late eclipse by Mr. Brothers. On examining the three images a nebulosity is observed, very similar to that in Mr. Brothers' photograph. In all three, taken at an interval between each of about a minute and a half, the nebulous appearance appears situated on three quarters of the limb, the remainder being quite free. There are also indications of a radial structure, so that he thinks it highly probable that the representations are actually those of the corona. Since communicating the above, he has carefully examined the two other photographs of the sun which he possesses, and which were taken early in the month of November 1858. These, one of which must have been exposed at about two hours twenty minutes after the other, present nothing remarkable to the naked eye; but when viewed through a glass of moderate power, a thin crescent-shaped envelope is observed on each, with this remarkable circumstance, viz., that in the two it appears on opposite limbs, suggesting the idea of a semi-revolution in the above interval of time at a velocity not much less than that due to Kepler's law of planetary motion. In one of the photographs there is, under the crescent and apparently on the rim of the sun itself, a narrow band in breadth about $\frac{1}{300}$ of the diameter of the disc, and of at least double the intensity of the sun. This may probably be referred to the actinic action of the chromosphere and the red flames.—"On Anthraflavic Acid, a Yellow Colouring Matter accompanying Artificial Alizarine," by Edward Schunck, Ph.D., F.R.S.

DUBLIN

Royal Dublin Society, March 20.—Professor R. Ball in the chair. Prof. Traquair read a paper on the restoration of the tail in *Protopterus annectens*. Two specimens of moderate size were exhibited and described, in both of which the caudal extremity of the body had been evidently truncated by violence, and a restorative process had taken place. In the first specimen the reproduced portion measured half-an-inch in length, and contained a prolongation of the notochord of the lateral muscle, and of the spinal cord, but neither vertebral arches, spines, nor fin rays. In the second the reproductive process had gone on to a much greater extent, the new portion being two inches long, and contained besides a notochordal axis, a reproduction of all the other essential parts of the normal tail of Protopterus. The neural and hæmal arches, spines, and fin supports were, however, entirely cartilaginous and rather irregular in their disposition. They were not traceable beyond a distance of one-and-a-half inches from the origin of the reproduced part, while the notochord extended to the very tip.—Dr. Moore read a paper on a Fungoid Disease which attacks and destroys plants belonging to the Pandaneæ; he also exhibited a specimen of *Silenipedium caudatum*, which had flowered in the Glasnevin Gardens for the first time in Ireland.—Professor Dyer read a paper on the Germination of Seeds. While it was true that in most Dicotyledons the root end of the embryo is developed into a tap-root, and that in most Monocotyledons the radicle was not developed, but the roots were pushed out through the base of the cotyledon; there could be no doubt that there were exceptions to this rule, which were both sufficiently numerous and important to be borne in mind, and which it was a great mistake not to find noticed in our Manuals of Botany. Many examples were given, such as palms with their exorrhizal roots, and Tropæolum with its endorrhizal roots. Prof. Dyer, in the course of his interesting paper, alluded to and illustrated Prof. Dickson's news on the embryo of Zostera.—Mr. W. F. Kirby read some notes on three species of trap-door spiders whose nests are in the Museum of the Society.—The Royal Dublin Society ordered a letter to be written to the Director of the Jardin des Plantes, Paris, informing him that Dr. Moore, Director of the Botanical Gardens, Glasnevin, had received instructions from the Council to assist as far as he possibly can in supplying the losses incurred by the recent bombardment.—A letter has been received by the Society from Prof. Milne-Edwards, stating that Prof. Decaisne will send over lists of their desiderata, and that in a few days the venerable Director of the establishment, M. Chevreul, will forward to the Society a letter of thanks for the warm sympathy and extreme kindness shown to the Jardin des Plantes by the vote of the Society.

EDINBURGH

Botanical Society, January 12.—Alexander Buchan, M.A., President, in the chair. "Note on the Practical Application of Meteorology to the Improvement of Climate." By Alexander Buchan, M.A. "Notes on the Structure and Measurements of Cells in Hepaticæ." By James Williamson Edmond, M.B. "Notes on the Distribution of Algæ." By George Dickie, M.D., Professor of Botany, Aberdeen. "On the Flora of the South of France." By Mr. James F. Robinson. "Memoranda on Fir Cones in the Museum at the Royal Botanic Garden." By Alexander Dickson, M.D., Professor of Botany, Glasgow.

PARIS

Academy of Sciences, March 20.—M. Faye, president, in the chair. Baron Thénard, who had been arrested by the Prussians as a hostage, was present at the sitting. After the reading of the *procès verbal*, he made a speech, in which he thanked the Academy for the protest entered by it against his arrest by Prussians when Paris was actually besieged by Prussian guns.—M. Chevreuil delivered a very long and very able speech on the changes of different kinds which silk undergoes from chemical agents when passing through different colouring processes.—M. Mathieu, the oldest member of the Institute, presented the *Annuaire des Bureaux des Longitudes*, which should have appeared on the 1st January.—M. Delaunay said he had been to inspect the Villejuif pyramid, which was erected on one of the extremities of the basis measured by Picard two centuries ago. The pyramid was not destroyed, owing to the precautions taken for its protection. The meteor of the 17th March was seen from several stations, viz., at Paris by M. Prevot, surgeon to the marines, at $10^h\ 58^m$, the luminous track remained visible for more than a hour; M. Samberg, Professor of Physics, at Rochelle, gives for the time $10^h\ 30^m$. The track was visible for an hour; no explosion took place. The colour was green, and the duration of the apparition was twenty seconds. Many sparks were noticed.—A discussion took place between MM. Delaunay, Becquerel, and Saint-Claire Deville on the temperature of the past winter. It was proved that the temperature is always less severe at the Jardin des Plantes than at the Astronomical Observatory, and that at the Astronomical Observatory it is less severe than at Montsouris. It results from this discussion that it is useless to attempt to find the absolute temperature of any region independently of local circumstances, and it is only by the comparison of many different observations that the facts relating to temperature can be ascertained.—M. Quatrefages presented a description of some helminthoid worms which locate themselves in the throats of snakes. These helminthoids cause such an irritation that the throat is closed, and the animal perishes by suffocation. In the secret committee, which was opened at five o'clock, a sharp discussion was raised between members with respect to M. Deville's proposition.

BOOKS RECEIVED

ENGLISH.—Essays on Darwinism: T. R. Stebbing (Longmans).—A Manual of Structural Botany: M. C. Cooke (Hardwicke).—Aunt Rachel's Letters about Air and Water (Longmans).—Dynamics of Nerve and Muscle: Dr. Radcliffe (Macmillan).—Cassell's Natural History, new ed. part I. (Cassell).

THURSDAY, APRIL 6, 1871

THE UTILISATION OF NATURAL HISTORY MUSEUMS FOR SCIENTIFIC INSTRUCTION IN GERMANY

IN the following notes we propose to consider the Natural History Museums in Germany, and to see to what extent and in what manner, indirect or direct, they are utilised for the scientific instruction or education of the people. These institutions are very numerous, there being one in nearly every larger German town, and even two or three in places like Vienna and Hamburg. Some comprise collections of zoological, anatomical, palæontological, botanical, and mineralogical objects, while others are limited to one or more of these branches, but whatever their contents may be, we do not recollect visiting one of these Museums in which the objects were left unnamed or unarranged. The majority are State establishments, under the direction of a single head, who is responsible to the Minister of Public Instruction. If the establishment is very extensive, the collections of the various branches are placed under more than one director, the administration and responsibilities being divided. Their development is in some measure dependent on the direct assistance of the Government, but still more on the energy and capability of the director, inasmuch as, of two Museums originally supported by the same grant of money, one has remained stationary for years, whilst the director of the other, making the best use of his independent position, has known how to raise the value of his Museum as a purely scientific or instructive institution, thus establishing claims for additional assistance, which could not be neglected by the Government.

We may divide the German Museums into—(1) Those founded with the intention of exhibiting objects of Natural History to the general public; and (2) those established for educational purposes.

There are not many of the former class. To it belong the Museums of the formerly independent "Reichsstädte," Hamburg, Bremen, and Frankfort-on-the-Main, one of the Vienna Museums, and the collections in Stuttgart and Darmstadt. There are others, like that in Mayence, but they have more the character of well-arranged local country museums. Although originally founded for the purpose of exhibiting curiosities, they soon took another position by receiving objects in which the general public takes a very limited interest (as, for instance, botanical, geological, or mineralogical specimens), and by systematically collecting materials for the purposes of purely scientific research. In several instances the scientific results were sufficiently important and extensive to form not only a nucleus but the sole subject-matter of distinct periodical works, such as the "Annalen des Wiener Museums," the "Museum Senckenbergianum," the "Abhandlungen des Hamburger Museums." The Frankfort Museum became the head-quarters for the Zoology of North-eastern Africa; Bremen possesses a unique collection of African birds, celebrated not only for the great number of standard specimens, but also for their beautiful state of preservation. In the Vienna Museum particular attention was paid to European fresh-water fishes; and travellers like Natterer, Russeger, Kotschy, enriched it with collections so numerous that the Austrian Naturalists have been engaged in their examination till within a very recent period. The Stuttgart and Darmstadt Museums are now celebrated for their valuable collections of South-German fossils, worked out by G. von Jäger, Kaup, and others.

In the Museums of this class great attention is paid to the local Flora and Fauna, recent and extinct. Thus the Stuttgart collection may be mentioned as a model of what a Museum ought to be; besides a most complete series of the plants and fossils, it contains a collection of the animals of Suabia in all stages of growth and development and of variation, in a perfect state of preservation, and particularly attractive from the life-like manner in which the specimens are mounted.

It was the natural consequence of the growth of a Museum, especially in the smaller of the towns mentioned, that it became a conspicuous object; that, although opened to the general public on certain hours of Sunday only, the crowds of visitors increased; that the interest in it spread into wider circles; and that, more or less in connection with it, societies were formed whose aim was the distribution of knowledge, and which were accessible to all. Although no great benefit is individually derived by the majority of the members of such societies from their rather superficial connection with Science, yet we ought to remember that even the fragments of knowledge picked up by them have the effect of expanding their ideas. A community of feeling grows up between the professed naturalist and the uninitiated, by which the former is encouraged in his further pursuits, and induced to consult in his labours and communications the requirements and understanding of the latter. Some of the German Governments, especially the Austrian, have also acknowledged the value of such societies by granting them an annual subsidy.

One out of several instances may be brought forward in evidence of the correctness of the above remarks, viz. the example of the town of Frankfort, to which many years ago a small miscellaneous collection and library was bequeathed, under the name of "Museum Senckenbergianum." By the able management and disinterestedness of Dr. Eduard Rüppell, it grew into a considerable zoological collection, of which the inhabitants were justly proud. An interest in Natural History being awakened, a body of men, chiefly wealthy merchants, formed themselves into a society, founding a Zoological Garden, and in connection with it a monthly periodical (noticed in one of our previous numbers), in which, at first, only objects of local interest were discussed, but which now has among its contributors eminent naturalists as well as amateurs, and does more for the distribution of sound natural history knowledge among the general German public than all the other scientific periodicals put together.

While thus we fully acknowledge the value of the Museums of this class as offering materials for really scientific original research, and as creating and maintaining an interest in Science among the general public, we understand that they are not utilised in a direct manner for methodical scientific instruction. Although Natural History is taught in nearly all the so-called Gymnasiums and Polytechnic Schools, the time devoted to it is limited, and those Museums are only visited at intervals by the classes under the guidance of teachers.

THE DESCENT OF MAN

The Descent of Man, and Selection in relation to Sex. By Charles Darwin, M.A., F.R.S., &c. In two volumes. Pp. 428, 475. (Murray, 1871.)

I.

IF Mr. Darwin had closed his rich series of contributions to Science by the publication of the "Origin of Species," he would have made an epoch in Natural History like that which Socrates made in philosophy, or Harvey in medicine. The theory identified with his name has stimulated ethnological and anatomical inquiries in every direction; it has been largely adopted and followed out by naturalists in this country and America, but most of all in the great work-room of modern science, whence a complete literature on "Darwinismus" has sprung up, and there disciples have appeared who stand in the same relation to their master as Muntzer and the Anabaptists did to Luther. Like most great advances in knowledge, the theory of Evolution found everything ripe for it. This is shown by the well-known fact that Mr. Wallace arrived at the same conclusion as to the origin of species while working in the Eastern Archipelago, and scarcely less so by the manner in which the theory has been worked out by men so distinguished as Mr. Herbert Spencer and Prof. Haeckel. But it was known when the "Origin of Species" was published, that instead of being the mere brilliant hypothesis of a man of genius, of which the proofs were to be furnished and the fruits gathered in by his successors, it was really only a summary of opinions based upon the most extensive and long-continued researches. Its author did not simply open a new province for future travellers to explore, he had already surveyed it himself, and the present volumes show him still at the head of his followers. They are written in a more popular style than those on "Animals and Plants under Domestication," as they deal with subjects of more general interest; but all the great qualities of industry and accuracy in research, of fertility in framing hypotheses, and of impartiality in judgment, are as apparent in this as in Mr. Darwin's previous works. To one who bears in mind the too frequent tone of the controversies these works have excited, the turgid rhetoric and ignorant presumption of those "who are not of his school —or any school," and the still more lamentable bad taste which mars the writings of Vogt and even occasionally of Haeckel, it is very admirable to see the calmness and moderation (for which philosophical would be too low an epithet) with which the author handles his subject. If prejudice can be conciliated, it will surely be by a book like this.

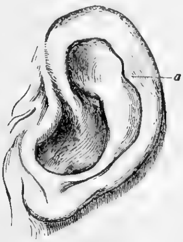
It consists of two parts. The first treats of the origin of man, his affinities to other animals, and the formation of the races (or sub-species) of the human family. Besides the obvious interest to all Mr. Darwin's readers of a discussion on the subject of their "proper knowledge," naturalists will find the detailed application of the laws of natural selection to a single common and well-known species an excellent test of their truth and illustration of their difficulties. It is in dealing with the latter, which are never extenuated or passed by, that the author introduces the subject of sexual selection. This is dealt with in the second part, which forms more than two-thirds of the work, and that not only as it affects man, but in its entire range. Reserving this division of the book for a future article, we will endeavour here to give a summary of the course of argument in the earlier portion.

The author, justly assuming that the general principles of natural selection are admitted by all who have examined the evidence on the subject, with the exception of many of "the older and honoured chiefs in natural science," proceeds at once to discuss the proofs of the origin of man considered apart from those affecting all animals in common. The first group of facts adduced to show his kinship with other forms of animal life, relate to the strict correspondence of his bodily parts with those of other mammalia. To say that these structures are the same because they have the same uses, is untrue, for many of them have no use in the sense of active function, and we constantly find the same structures in animals turned to different uses, and the same uses subserved by different structures. To say that the bodies of men and animals are alike because they are formed on the same plan, or because they are the realisation of the same idea in the Creator, is true enough, but is beside the mark; for natural science inquires how or by what steps these things have become so, not why and from what first cause. If one sees two men very much alike, one naturally supposes that they are brothers; if they are rather less so, they may be cousins; if only agreeing in general characters, we recognise them as at least belonging to the same race or nation; and so, when the facts to be accounted for are once ascertained, nothing but prejudice or repugnance to acknowledge our true relations, can explain why it was so long before naturalists admitted the hypothesis of community of origin between men and other animals. What is called the Darwinian theory accounts for the way in which diversities have arisen, and thus has converted an apparently obvious hypothesis into a well-grounded theory. But in expounding the likeness between men and animals, the author does not confine himself to anatomical structure, but shows how the same resemblance extends to the laws of disease, the distribution of parasites, and other minute particulars.

The next argument brought forward is the equally familiar one drawn from the likeness of the human embryo to that of other vertebrata. Then follows an account of the rudimentary organs in man, which in all other species are justly held among the most important indications of affinities. One such rudiment is mentioned which is, we believe, hitherto unrecorded. It is a slight projection of the rim of the helix of the auricle, which would correspond when unfolded to the point of an erect ear. (See illustration.) This occasional abnormity may, perhaps, be recognised by future anatomists as the *Angulus Woolnerii* after its first observer.

In the second chapter Mr. Darwin shows that a consideration of the mental faculties of man, including the use of language, which has been held the greatest difficulty to admitting his kinship to other animals, may rather strengthen than weaken the arguments derived from his bodily structure. Memory and curiosity, jealousy and friendship, and even the power of correct reasoning, and of communication by sounds, are shown to belong to many of the lower animals, while the faculty of reflection and self-consciousness, and "the ennobling belief in the existence of an Omnipotent God," cannot be ascribed to the lowest tribes of the human family. At the same time it is argued that the use of articulate language, the power of forming abstract ideas, and even the sense of right and wrong, may have been gradually acquired by steps which here and there it is not impossible to trace. The question of the origin of the moral sense leads to the proposition of the following theory. Some natural emotions are of great intensity but short endurance, and their force is not easily recalled by memory; others, though less powerful at certain times, exert a constant influence, or one which is only interrupted by being overpowered for a time by the former. Accordingly, during the greater part of life, and always when there is leisure for reflection, the gratification connected with the more violent passions, such as hunger, sexual desire, and revenge, appears small, whereas the social instincts of sympathy and the pleasures of benevolence exert their full power. Hence we find social virtues, as courage, fidelity, obedience, among savages and even animals, long before the "self-regarding" virtues begin to appear. This theory is analogous to that by which Mr. Bain explains the higher character of the pleasures of sight compared with those of smell; they can be more easily recalled ;and corresponds to the distinction drawn by the same writer between the acute and the more "massive" and permanent pleasures.

In the fourth chapter Mr. Darwin discusses the manner in which man was developed. It is shown that the broad facts on which the theory of Natural Selection rests apply



Human Ear, Modelled and Drawn by Mr. Woolner. *a*. The projecting point.

to him. He is prolific enough to share in the struggle for existence. In him, as in all organic forms, there is a constant tendency to growth, which being checked and modified by external influences, proceeds in the direction of least resistance, and so produces the variations which are often ascribed to an assumed inherent tendency. Among the various forms produced, those will survive which are best fitted for the surrounding conditions, and they will transmit their character to their descendants, still subject to the same liability to vary. Next the author argues that the mental endowments of man, including language, his social habits, his upright position, and perfect hands, are of direct advantage to him in the struggle with other animals and with his fellows. It has always appeared that the difficult point in the development of man by Natural Selection is at the period when he was more defenceless than an anthropoid ape and less intelligent than the lowest savage; but Mr. Darwin thinks that the transition may have been safely made in some large tropical island where there was abundance of forest and of fruit. That man, once developed, can maintain himself, is obvious from his present existence. The arguments in favour of civilised man being the descendant of savages, which have been so admirably developed by Sir John Lubbock and Mr. Tylor, are of course brought forward in support of the author's view, and the important question is discussed how far we may hope for future improvement in the race by means of continued Natural Selection. Thus, while admitting that the process undergoes many checks and complications among human beings, the author does not assent to the arguments urged by Mr. Wallace that it would cease to operate as soon as the moral faculties came into play.* One human peculiarity which is apparently inexplicable by Natural Selection, the nakedness of the body and presence of a beard, is referred by Mr. Darwin to the operation of Sexual Selection. To this same agency is attributed the origin of the so-called Races of Man, which is discussed with admirable clearness and impartiality in the last chapter, and this leads to the complete exposition of the theory of Sexual Selection which occupies the second part of this work, and must be considered in a future article.

It only remains here to add a word on the account of the affinities and genealogy of man contained in the sixth chapter. As a kind of retribution for the attempt to raise Cuvier's order *Bimana* into a sub-class, not only have most naturalists now reverted to a modified definition of the *Primates* of Linnæus, but Mr. Darwin shows reasons for refusing to the genus *Homo* even the rank of a family in this order, which Prof. Huxley admits, and regards it simply as an aberrant member of the Catarrhine division of the *Simiadæ*. This conclusion, which seems to us to be a just one, will only be distasteful to those who so little appreciate the true characters of man as a spiritual being, that they could feel self-complacency in the brevet-rank of a sub class.

Mr. Darwin mentions Africa as the possible seat of the Catarrhine progenitors of man, but shows the futility of speculations on this point, until we know more of the recent changes of the earth, the records of palæontology, and the laws affecting the rapidity of animal modifications. He does not advert to Prof. Haeckel's hypothesis of a "Lemuria" in the Indian Ocean, but agrees with him in next tracing the phylum of man to the *Prosimiæ*. These again were developed from "forms standing very low in the deciduate mammalian series" (possibly, as Prof. Huxley suggests, most nearly allied to the existing *Insectivora*), and thus, through the Marsupials and Monotremes from the Reptilian stock, and thence through the *Dipnoi* and Ganoids from the *Urtyhus* of the vertebrate series, represented by the Lancelet alone. Nor does Mr. Darwin stop here, but adds the weight of his judgment to the theory based on the observations of Kowalewsky and Kuppfer, which deduces the primeval *Vertebrata* from a form resembling a Tunicate larva. Perhaps the most brilliant of the many new suggestions in these volumes is one thrown out incidentally in a note to p. 212, and based upon this supposed relation of man to the Ascidians. Beyond the organic world Mr. Darwin does not attempt to trace the genealogy of man. Considering how essential this extension of the theory of evolution is held by men so distinguished as Haeckel, and how keenly the question

* In reviewing in these columns the contributions of the latter eminent writer, we took occasion to quote the estimate he expresses of Mr. Darwin's claims. Should anyone be disposed to overlook the original value of Mr. Wallace's work, he will be corrected by a somewhat similar passage in the present volume. See pp. 137, note, and 416.

of Abiogenesis has recently been discussed, the reticence shown in avoiding allusion to the subject is perhaps the most remarkable among the many remarkable characters of this great work. P. H. PYE-SMITH

OUR BOOK SHELF

Elementary Natural Philosophy. Being a course of nine lectures by J. Clifton Ward, F.G.S., Associate of the School of Mines. (London: Trübner and Co.)

THE attempt to crowd the Elements of Natural Philosophy into nine lectures cannot be otherwise than a failure. This is signally the case with the little book before us. We need hardly go farther than the table of contents to justify the statement. A single lecture is devoted respectively to Magnetism, Voltaic Electricity, Light, and Heat; Pneumatics and Hydrostatics together occupy one lecture, whereas to Frictional Electricity and Sound are given two lectures apiece. Nor does the author confine himself to a simple summary of the leading facts in each of these subjects, he tries to rush over all the field occupied by larger text-books. Hence, important facts are often lightly passed over and comparatively trivial matters made unduly prominent. In Voltaic Electricity, for example, two pages are occupied with a description of the effects of electro-chemical decomposition, when seen on the screen by the aid of the solar microscope. We recognise here, and indeed on every page of the book, those lecture-experiments with which Dr. Tyndall has made the students of the School of Mines so familiar. Mr. Ward has not only drawn largely upon his notes of those lectures, but he imitates Dr. Tyndall's language and style.

Notwithstanding this, we are quite sure Mr. Ward has only himself to blame for the errors which even a cursory glance has revealed to us. On p. 85 we read "Magnetism may be produced by *friction* (of *soft iron* with loadstone or other magnet) by magnetic induction and electricity." Magnetism is *not* produced by friction of soft iron. On pp. 36 and 37 Mr. Ward has fallen into a vulgar and serious error in explaining the electric wind. Speaking of the so-called electric fish, here is what he says:—"If the interior of the Leyden jar be charged positively, negative electricity will be attracted to the head of the fish, from the somewhat blunt point of which it will stream and cause a movement from the knob; while the gliding off of the repelled positive from the finer pointed tail, will counterbalance this movement, and keep the body in equilibrium." The author also speaks of a lighted candle extinguished by the *draft of electricity* streaming from a point. This, of course, is grossly incorrect; it is the movement of contiguous air particles charged similarly by contact and then repelled, that extinguishes the candle, or supports the gold leaf fish.

Though there are some good points in this little book, we regret our inability to recommend it either to schools or students. We venture to think the author betrays his want of experience in teaching science by the over-crowding of his facts; the first lecture, for instance, is accompanied by thirty-three distinct experiments. Teaching—especially science teaching—requires "precept upon precept, line upon line, here a little and there a little:" otherwise there is an almost certain danger of the learner obtaining loose and superficial knowledge, the end of which is not sound instruction, but disastrous conceit.

W. F. B.

Essays on Darwinism. By J. R. R. Stebbing. (Longmans and Co., 1871.)

MR. DARWIN, in his recent work, very truly observes that "false facts are highly injurious to the progress of science, for they often long endure; but that false theories are comparatively innocuous." Mr. Stebbing's work can then do little harm, as it supplies us with no new "facts" whatever, whether true or false. The author is an advocate who serves Mr. Darwin with more zeal than discretion, and who seems but little, if at all, able to appreciate the arguments and objections adduced on the other side. Some who are already convinced of the truth of Darwinism will read with pleasure a series of eloquent and interesting essays in its favour; but, though calculated to confirm a disciple, they are singularly ill-calculated to convert an opponent. Before Mr. Stebbing again writes upon this subject we strongly recommend him to peruse carefully Mr. Grote's "Examination of the Utilitarian Philosophy."

Das Wesen und die Ziele der Chemischen Forschung und des Chemischen Studiums. Akademische Antrittsrede gehalten von Dr. Rudolph Fittig. (Leipzig: Quandt and Händel, 1870. London: Williams and Norgate).

So busy are the majority of German chemists in research, that it is seldom we are privileged to have their opinions on the object of the science, and the position it should occupy as a study. Dr. Fittig has availed himself of his appointment as Professor of Chemistry in the University of Tubingen to deliver an inaugural address, in which these points are discussed with great clearness and ability. Starting with the assumption that the majority of men estimate the value of a science only by its power to satisfy want and contribute to the comfort of life, Dr. Fittig goes on to claim for chemistry from this point of view the first place among the sciences. "Where," he asks, "is there another science which, in the application of its results to man, almost from his first breath to his last, is so true a companion as chemistry?" and he proceeds to show that it is useful, not so much in explaining what the nourishing constituents of food are, as in disclosing the laws of agriculture, and thus teaching us how to produce means of nourishment. Further, he points out that there is not an article of clothing for the preparation of which chemical knowledge has not been employed, and the same knowledge is necessary to show how the spread of disease may be prevented, and cured when it has taken hold. While these practical results are obtained by the study of chemistry, Dr. Fittig is careful to show that it is a total misunderstanding to suppose that its chief purpose is to discover brilliant colours or new medicines. Thus, without undervaluing the practical importance of the discovery of the aniline colours, it is nevertheless true that the splendid results obtained by Hofmann would have had the same interest for the chemist, had these compounds been colourless and without any technical use. So we are told, "The task of chemistry is to explain the composition of bodies and all phenomena resulting from change of this composition *in order to derive the regular connection and cause of these phenomena, and therefore also of the natural laws which regulate the building up and decomposing of substances.* . . . . We are compelled to multiply the number of substances already existing in nature, not for the sake of producing new bodies and benefiting the world, *but to discover the eternal laws of nature.* He is no true chemist who only prepares new compounds without any definite aim (although, perhaps, he has prepared a large number of compounds hitherto unknown and possibly very beautiful in appearance), and his work has no direct value for science, and can only become valuable when employed by others in its true scientific sense. . . . . True scientific researches must never be given over to chance, they must be systematically planned, begun with a clear consciousness of what is to be attained, and finished in the same spirit." Dr. Fittig has done well to point out so clearly the true aim of the science of chemistry, and to disparage the false estimation of its value, which would make it simply a means of discovering bodies with some technical or useful application. And even in this direction, which must always be looked upon as of secondary importance, we are convinced that greater progress will be made if chemistry is regarded and studied from the high point of view so forcibly pointed out by Dr. Fittig in his interesting address. LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Chemical Research in England

IN confirmation of your remark in the last number of NATURE that, in regard to scientific discovery, we in this country "are conspicuous for our prominent position in the rear," will you permit me to state the result of an inquiry which I lately made into the comparative activity of this and other countries in the prosecution of chemical research?

In the year 1866 there were published 1,273 papers on new discoveries, by 805 chemists, 1·58 paper being thus the average produce of each investigator. Of these, Germany contributed 445 authors and 777 papers, or 1·75 paper to each author; France, 170 authors, and 245 papers, or 1·44 paper to each author; whilst the United Kingdom furnished only 97 authors, and 127 papers, or 1·31 paper to each author; all other countries yielding 93 authors and 124 papers, or 1·33 paper to each author. Thus, not only are we far behind in the aggregate of activity in discovery, but our individual productiveness is also markedly below that of Germany and France. From a purely national point of view, our case is even worse than it appears to be from a comparison of these figures, since a considerable proportion of the papers contributed by the United Kingdom were the work of chemists born and educated in Germany.

It will be seen that the above comparison covers chemistry only; but there is every reason to believe that in other sciences, the progress of which depends, like that of chemistry, upon experimental investigation, our position is still worse. It is highly remarkable that a country which, perhaps more than any other, owes its greatness to the discoveries of experimental science, should be distinguished for its neglect of experimental research. But the causes of this anomaly are sufficiently obvious; they are:

1st. The want of suitable buildings and apparatus for the prosecution of such investigations.

2nd. The non-recognition of experimental research by any of our universities.

With regard to the first of these causes, the prosecution of experimental discovery in this country is rendered extremely difficult, if not impossible, to those who do not possess ample private fortunes; and even to such as have this advantage, it is by no means easy. A laboratory of research is not a convenient or agreeable adjunct to a dwelling-house, and it is generally prohibited by the terms of the lease or covenant; indeed it is agreed on all hands that most of the operations which are required for the prosecution of inquiries in chemistry, physics, and physiology, ought only to be carried on in buildings specially devoted to the purpose. But where are such buildings to be found? Our chemical laboratories are only adapted for beginners, there is not in any one of them a separate department constructed and fitted for original research. Still less is this the case in physical and physiological laboratories; indeed until Sir William Thomson instituted one in Glasgow some three or four years ago, there was not in the United Kingdom a physical laboratory even for beginners. In Germany, on the other hand, the noble State laboratories of Berlin, Leipzig, Bonn, Heidelberg, Königsberg, and Stuttgart, are provided with special departments where the experimental investigator finds ample convenience and the necessary but costly instruments of precision provided for his use, the payment of a moderate fee only being required to secure all these advantages.

With regard to the second case, the highest degrees, and even honours in experimental science, are given in all our universities without any proof being required that the candidate possesses the capacity to conduct an original experimental investigation, or that he is competent to extend the boundaries of his science. On the other hand, in all the Prussian Universities, and in the best German Universities generally, no candidate is even admitted to examination for his degree unless he first submits to the senate a dissertation on some original experimental investigation conducted by himself. This investigation must also have a sufficient importance; for, as a matter of fact, more candidates are rejected on the ground of insufficiency of dissertation than through failure to pass the subsequent examinations. The entire ignoring of research in the granting of degrees in this country not only effectually prevents the training of students in experimental investigation, and the actual execution of researches by students; but it has also a direct tendency to divert the attention of professors and teachers from original research—they are not called upon to devise, as is the case in Germany, suitable subjects for research to be pursued by their students; and thus, not only is their attention withdrawn from this all-important field of experimental science, but, as their students have to be trained for subjects which are foreign to research, they feel that to devote any considerable portion of their own time to it would be to that extent to neglect their class duties.

E. FRANKLAND

Dublin Observatory

IN an account of the Observatory of Trinity College, Dublin, given in NATURE of March 16, 1871, there is a slight mistake in the date of the erection of the Transit Instrument, which is there assigned to 1808. It was erected many years before; for in the second volume of the Transactions of the Royal Irish Academy, Dr. Usher describes observations made with it in 1785.

I should not have thought the correction of this error necessary but for the fact that this transit marked the epoch of a most important improvement in astronomical instruments. It was the first in which the illumination of wires was effected through the axis by an internal reflector. This invention is described by Usher in the volume already referred to.

1808 was the date of the circle's erection; it having been ordered in 1783. This delay was in one respect fortunate. Ramsden, having quarrelled with Usher, resolved that the latter should never have the circle. On Usher's death Ramsden set to work to complete it, but found, to his dismay, that the extremities of its radial arms had become "rotten," having been acted on by the sulphurous atmosphere of London.

As originally constructed, it was ten feet diameter. He removed the rims (which, I believe, had been also acted on), cut away about six inches from each of the arms, and found the remainder sound. But as he was doubtful about its permanence, he let it lie several years longer, and found his apprehensions verified. He cut off six inches more from each arm and awaited the result, notwithstanding the urgent expostulations of Brinkley; and it was not until a short period before his death that he was satisfied that no farther change was probable. He then completed it at its reduced diameter of eight feet. But it was not divided till after his death (by Berge, his successor).

It is not easy to explain why this destruction was confined to the ends of the arms. To judge from the analogy of the Palermo Circle, the diameter of these arms at the outer extremity was very small; and if they were of cast brass, the molecular condition of the metal there, in consequence of the more rapid cooling, may have been different from that of the more massive portions.

A still more remarkable instance of this destructive action occurred to a circle described by Mr. Bond in the Philosophical Transactions, 1806, and known as the Westbury Circle. This was ultimately established at the old Observatory of the Glasgow University, and in an atmosphere still more sulphurous than that of London. When this University was broken up, and its instruments sold, this circle was purchased by the late Sir James

South. But on its arrival at his Observatory it was found to have suffered so much that it actually fell to pieces! Only a few of the more massive parts were entire; and of the rims of the circle nothing remained except that which carried the divisions, which, as I was informed by Troughton, was of "Dutch brass," and was quite unchanged.

The excellence of this Dutch brass is, I believe, recognised also by watchmakers, and it seems to deserve inquiry to what its superiority over English brass is to be attributed.

It is worthy to be mentioned that among the instruments ordered from Ramsden by Usher was an equatorial telescope driven by clockwork. But owing to Ramsden's feud with Usher, this was not executed; and this important aid to the astronomer, which had been proposed by Hook nearly a century before, lay dormant till it was applied by Frauenhofer, forty years later, to the Dorpat telescope. Armagh

Morell's Geometry

In answer to your criticisms on my work, "The Essentials of Geometry," I have given an explanation as to the sources of that book. I proceed to give very briefly my arguments for what is there advanced.

I shall do so under two heads, which will be in the form of indictments against my reviewer.

For I charge him, first, with overlooking the nature and object of the book; and, secondly, with overlooking the context of passages he criticises, an omission that changes the entire aspect of the case.

First it is explained (Preface, p. vii.) that my little volume is an attempt at a manual and memento for students, of which so many exist in France and Germany. It is notorious that such works do not dispense with others, or touch the plan of school text-books, and then much of their contents consists of results with hints of demonstrations. Then at p. viii. of Preface it is added that an inspection of the methods employed will show that German and French geometricians . . do not condemn the student to keep a geometrical figure rigidly in the place in which it is laid down on paper. Revolution and superposition are allowed . . . simplifying and shortening the proof, &c.

Passing to the second indictment, I find that the criticism levelled against my so-called theorems of parallels commits two serious offences. First, it garbles my matter; secondly, it overlooks the principles first laid down in the preface, applying from logic two propositions treated by me both manually and logically; thirdly, it overlooks claims in pp. 15, 24, 25, where the technical terms in p. 20 are explained; lastly, it ignores the fact that all our theorems about parallels rest on assumptions and not on logic.

It is evident that if superposition be allowed, two parallels as they cannot cut (hyp) must coincide, thus the angles they form with a secant will be equal.

Again, the charge of want of logic in my proof of the inequality of triangles with three equal sides falls to the ground, if the first clause of p. 44 be read. For as this is a case of superposition by making the bases coincide, the arms of both triangles must coincide as radii of equal length intersecting at only one point on the same side of the base. The proof is equally direct from symmetry, from inversion and juxtaposition, and from subposition, as in the Notes to Todhunter's School Euclid.

As to the critic's difficulties about explaining the coincidence of two semicircles, to any one used to the free handling of geometrical figures in France and Germany, the thing wears a ludicrous aspect.

Then about the statement that two equal adjacent dihedral angles are right angles, a moment's reflection shows that if a dihedral angle be defined (Bos. p. 32) as an angle formed by the revolution of a movable plane at its common section over a stationary plane, when it reaches the point where the two adjacent angles are equal, they must be right angles. The definition may be disputed, but the conclusion is correct.

As regards the criticisms on my definitions, I do not think it necessary to enter into this matter. The ground of definitions is a wide and a disputed one, and I am content to err, if err I do, with very high authorities. Euclid has defined a straight line to be that which lies evenly or equally between its extreme points. This definition affords no assistance in arriving at the properties of straight lines. In Dr. Simson's edition, a point is defined to be that which has no parts or no magnitude. This is objectionable, as being wholly negative. Again Dr. Simson, in the notes to his edition of Euclid, admits that the 11th axiom is not self-evident.

In conclusion, the reviewer is of course as likely to attack the free treatment of theorems and problems practised, especially in Germany, by the conception of the generation of all figures from their elements by the movement of points and lines. But it can scarcely be charged against the author of the "Essentials" that he has not shown some of these shorter methods of demonstration as used in France and Germany.

The nature of revolution is fully illustrated at pp. 6, 8, and the treatment of angles as ratios in note 2, p. 9. Our limits prevented anything more than indications, but *verbum sat.* to the great logicians of England. J. R. Morell

On the Derivation of the name "Britain"

Having been from home, I did not see the letter of "A. H." in your publication of March 16 until yesterday. His only objection to my derivation of the name *Britain* is that the word *tin* in his opinion was "not used in this island so early as the argument for its forming part of the word *Britain* requires. The following remarks will show that it *must* have been used in this island quite as early as the word *Britain*.

His assertion that "our word *tin* is of comparatively modern formation," cannot be established. It *must* have been familiar to the Cornish centuries before Diodorus Siculus described St. Michael's Mount, in Cornwall, under its name of *Iktin*, from whence tin was exported by the Phœnicians as far back as the time of Moses (Numb. xxxi. 22); and from none but the Phœnicians could the Cornish have derived the word *tin*—for that metal, as well as its name, was unknown to them before they were visited by the Phœnicians. The name *Iktin* (Tin-port) by which the Mount was called in the time of Diodorus, proves the existence of the word *tin* prior to that period, and the present Cornish word *stean* can only be a corruption of the very anciently adopted word *tin*—a corruption arising probably during the Roman period, so that instead of *tin* being a corruption of the Welsh *ystaen*, or of the Latin *stannum*, as "A. H." imagines, the reverse is evidently the case.

Assuming, with most authors, the original Phœnician word to be *tin*, that name continues unchanged in the Saxon, English, Dutch, Danish, and Icelandic languages; but the Swedish name is now *tinn;* the German, *zinn;* the French, *étain* and *tain;* the Latin, *stannum;* the Italian, *stagno;* the Spanish *estano;* the Portuguese, *estanho;* the Irish, *stan;* the Welsh, *ystaen;* the Cornish, *stean;* the Armoric, *stean* and also *staen*—the initial letter or sound *s* in each of the last nine names being a mere prefix, as in the modern word *sneeze* for *neeze* (Job xli. 18). With this exception, and except the ordinary terminations of the Latin, Italian, Spanish, and Portuguese names, these thirteen different spellings are merely the different ways in which different nations of Europe pronounce the Phœnician word *tin*.

Diodorus speaks of *Iktin* as an island adjoining *Britain;* and this island (for it *is* an island two-thirds of the day) was no doubt long before his time called sometimes *Iktin* and sometimes *Bretin;*—*Iktin* when it was regarded as a "port," and *Bretin* when regarded as a "mount"—*ik* being the Cornish for "port," and *bre* the Cornish for "mount." It was however most generally known as a mount, and as the most remarkable object in *Mount's* Bay, to which it has therefore given its *English* name, having long before the Christian era, in all probability, given its ancient Cornish name of *Bretin* to the island in which we live.

Plymouth, March 29 Richard Edmonds

Records of European Research

The Chemical Society has taken up a good cause, that of reporting foreign labours much more fully than could be worth the while for any periodical publication to undertake.

I have suggested in another quarter the advisability, if possible, of joining in this scheme. But funds are requisite to have the work well done.

It has struck me that, as a matter of completeness and economy, it would be far better if the learned societies subscribed, and the Royal Society made a grant besides its subscription, to engage an efficient staff to report foreign contributions not merely to one branch of science, but to all, forming, let us say, a quarterly *comptes rendus* of European research.

The practice of quoting the titles of foreign papers is aggravating in the extreme, especially when accompanied by the remark that "this laborious but lengthy paper is not suited for 'abstraction!'"

I seldom go out of our foggy little island without hearing our want of familiarity with what is going on elsewhere roundly and deservedly abused. But I feel bound to say that, more especially in France, I can justly retaliate.

Russian science is said to be very productive. That language, at all events, is beyond most of us.

Aurora Australis

OBSERVING in NATURE of Oct. 27, an account of a brilliant aurora observed in England on the 23rd to the 25th of that month, I think it may excite attention to the subject by informing your readers that at the same date a splendid display of Aurora Australis was recorded at most of the meteorological stations in this colony.

The extent of sky covered was not so great as in the fine display on 5th April last, which was also coincident with a remarkable Aurora Borealis, but the red tint was so much deeper than usual, that many persons in this place attributed the phenomenon to the glare of the great fire which destroyed the town of Lyttelton, and the news of which was just then received by telegraph. Ocean Currents

MY rejection of the idea that permanent differences of atmospheric pressure could produce any effect on Ocean Currents, was meant to be as sweeping as Mr. Johnston considers it. I believe that the idea is repugnant to the most elementary conceptions of hydrostatic equilibrium; and I am particular in so far repeating the gist of my former letters, because Mr. Johnston, in his letter in NATURE for March 9, reiterates his suggestion that difference of atmospheric pressure is a power in the production of Ocean Streams, and whether he suggests that it is a supplementary power, or a chief one, is nothing to the purpose, if, as I distinctly maintain, it is not a power at all.

My rejection of the idea that the formation of these differences of pressure can produce any appreciable effect, is quite as decided; but Mr. Johnston is mistaken when he speaks of my denying also the influence of the movement of these differences of pressure; for my remarks concerning them were to the very opposite purport; and I pointed out that such movements do sometimes give rise to rapid and dangerous sets, known as storm-currents, which in their irregular and exceptional nature, differ essentially from those regular permanent or periodic currents usually understood by the general term Ocean Currents, though they may occasionally modify them both in direction and velocity.

I would also call Mr. Johnston's attention to the fourth paragraph of his letter, and assure him that I have never, directly or indirectly, maintained that the Trade Winds "would account for the whole of the phenomena of Ocean Currents;" but I have maintained, and do still maintain, that all the phenomena alluded to may be very satisfactorily accounted for by a reference to the prevailing winds of the different parts of the world; and that the Gibraltar Current is to be attributed, not to the local, partial, and peculiar wind of the Straits, but to the great body of the west wind of the North Atlantic, which also produces a northerly current on the coast of France, known distinctively as Rennell's Current, and a southerly current on the coast of Portugal.

I have discussed this question so fully in another place, that I should be only repeating myself were I to say more about it here; but I may add that though, as Mr. Johnston asserts, under-currents cannot be caused primarily by the action of the winds, they can be, and frequently are, caused secondarily by that action; and many a ship has owed her safety from the apparently imminent danger of a lee-shore, to the "under-tow," or reflux of the water swept towards the shore on the surface. If there is a deep-flowing outward current in the Straits of Gibraltar, I believe it to be exactly of the nature of an "under-tow;" it seems to me probable enough that there is occasionally such an outward current; but I cannot admit that the *one* observation of it which Dr. Carpenter considers he obtained, after several attempts made in vain, has abundantly proved its existence; still less can I admit that it is necessary to call in difference of temperature and density to account for it.

Mr. Croll considers that there is a similar escape of water, underneath, from the northern to the southern hemisphere, and his arguments appear to warrant the suggestion, although no such under-current, or system of under-currents, has yet been observed. I see no improbability in the idea; but so many mistakes have, at different times, been made by trusting rather to theory than to positive evidence of fact, that we cannot be too cautious in admitting the existence of such under-currents, without any reliable observations. For that recorded by Captain Maury, to which Mr. Johnston refers, has, from the vague manner in which it is described, no scientific value whatever. There is no mention of locality, season, direction of wind, swell or surface current, no mention of the relation between the effective area of the "block of wood loaded to sinking" and the barrega or breaker which floated it; the depth is spoken of as indifferently one hundred or five hundred fathoms; above all, no mention is made of any means being taken to distinguish between an apparent and real set of the breaker. It is quite clear that if the loaded block was lowered into still water, the breaker to which it was attached was, to a certain extent, moored, and the surface drift of the boat away from it would give it all the appearance of moving in the opposite direction. No mention is made of the method adopted to discriminate; or, in fact, of any method at all being adopted, or any attempt made to eliminate or neutralise the many errors which necessarily find their way into such an observation; all that we are told is that "it really appeared as if some monster of the deep had laid hold of the weight below, and was walking off with it." To such an account one is almost attempted to add—very like a whale.

I have dwelt on the thoroughly unsatisfactory nature of this experiment, because, from the description of it having been repeated in every edition of the "Physical Geography of the Sea," I find it constantly referred to—as Mr. Johnston has now referred to it—as a conclusive proof of the existence of strong counter under-currents at great depths; whereas in reality it is a proof of nothing, unless, perhaps, of the careless style of observing which was accepted as sufficient twenty years ago.

The other instance which Mr. Johnston brings forward would be really remarkable, if we only had some evidence of it as a fact; he speaks of the warm water of the Atlantic dipping down beneath the cold and "specifically lighter" water of the east Greenland current. It has been well known, long before the late German expedition, that at the meeting of the two waters there is a distinct line of demarcation, but such a line does not necessarily indicate a dip of either water, such as Mr. Johnston describes; as indeed has been very fully shown by the survey of the nearly vertical "cold wall" of the United States, along which the line of demarcation is more distinct than anywhere in the world. And besides, can we admit that the water of the East Greenland current is "specifically lighter" than that from the Atlantic? that the cold water is lighter than the hot, the salinity of the two being very nearly equal? Captain Maury speaks of hot water, like oil, running over cold; Dr. Carpenter illustrates the same idea in a long glass trough, showing plainly enough the way in which he conceives the interchange to take place. I do not attach so much value as Dr. Carpenter does to this illustration, which represents a system of motion entirely different from that of the ocean-currents; but accepting it as the exposition of the views held by the leading supporters of the claims of temperature and density, it is utterly antagonistic to the idea of this extraordinary dip of warm water said to take place near the east coast of Greenland. Whether we consider it from a purely theoretical or from a geographical point of view, the idea is wholly unsupported, and can only be classed as one of those crude speculations which, in every branch of science, do so much harm by tending to unsettle the minds of those who indeed take an interest in the subject, but have not made it a special study. J. K. LAUGHTON

Draper's Experiment simplified

WISHING to repeat Draper's Experiment, and casting about for a simple method of performing it, it occurred to me to take advantage of the intense heat evolved in the combustion of sodium, and, beginning with the entire spectrum, watch its degradation as the heat declined; to which end I formed a shallow, conical cup of thin copper wire, half an inch in diameter, and, putting therein a piece of sodium, applied a spirit-lamp till it burst into flame; very soon the mass melted and rose to an intense, white heat, the air streaming in through the spiral greatly favouring the combustion, a full spectrum of the utmost purity and splendour was formed, which continued as long as the white heat lasted, but afterwards declined from, and rapidly at, the violet end through the whole spectrum to the red, which persisted longest. On repeating the experiments, and raising a very narrow slit to the spectroscope, I found, as I anticipated, the sodium line reversed, and I had before me a miniature sun, a glowing centre emitting light of every wave-length, while the melted sodium, flowing through the intervals between the wires of the lower part of the cone and being dissipated by the heat, surrounded the liquid centre with an atmosphere absorbing light of its own refrangibility.

Thinking some of your readers would like to repeat so simple and inexpensive an experiment, I have ventured to send you this. T. F.

Entomological Queries

CAN any of your entomological readers refer me to any works or memoirs on British Ants published since the appearance of Westwood's "Classification of Insects," and not quoted by Mr. Smith in his volume on "Formicidæ" in the British Museum Catalogue? What is the scientific name of the Texas agricultural ant and of the smaller ant which it ejects from its colonies? And where can I find M. Lespes' paper or papers on the "Domestic Economy of Formicaries," especially with regard to the Clavigers and other blind beetles? A. EMMET

Feb. 21

Rain produced by Fires

IN your No. of Feb. 16, there is a letter from Mr. Laughton on the Artificial Production of Rains, which is worthy of notice from a strictly scientific point of view. I have little doubt that rains have been in comparatively rare cases caused by large fires. We may dismiss from our minds the idea that rains can be produced, even when the conditions are favourable, by all the powder that is burnt during a battle on land or sea. It is said that "in a problem of this nature, negative examples have more weight than positive." But it is surely more philosophical to hold that the one class of instances is as valuable as the other. If rains have sometimes been produced by fires, it is as well to try to eliminate the conditions under which they occur as in those cases in which they do not occur.

It is curious enough that much of the popular belief as well as a disbelief in the connection between rains and fires must be ascribed to the late Prof. Espy. After laying down with scientific accuracy the atmospheric conditions for such an occurrence, he somewhat lost sight of the principles in his instructions to the farmers of the United States for burning their felled timber for the production of rain. I need not enter into these. The negative cases are found to be numerous enough. Great fires rage over the Prairies and through the woods in America for weeks during the autumn, and the air becomes darkened by a veil of smoke, while no clouds are to be seen. This usually occurs when the wind is from the west and the air dry, and naturally blue and bright till obscured by smoke. In such instances the theory of fires producing rains justly enough becomes unpopular.

On the other hand Espy laid down with great precision the conditions under which rains will result from great fires in "a high dew-point and a calm atmosphere." In short, the air must be pretty well saturated with moisture, and verging upon that unstable state of equilibrium under which cumulus clouds are formed. As Espy has shown, and every observer of the phenomena will confirm, the gorgeous cumulus clouds of summer are not seen when the air is much disturbed by winds. Their very formation and existence depend upon ascending currents. Previous to Espy's investigations, it was supposed that the formation of cumulus was due to the expansion of the vapour of water by the heat of the sun and its consequent diffusion upwards through the permanent gases till it was condensed above. He clearly showed by experiment that vapour has little power of permeating air under the ordinary pressure of the atmosphere. And he drew the inference that it could be only carried into the higher strata by ascending currents. This, I think, is amply borne out in the formation of all clouds.

Fires then, are only likely to produce rains during comparatively calm weather. In the positive instances given by Espy, most of the observers state that the air was calm and sultry. One of the staff of the United States surveyors when in Florida mentions, that by firing the bush "whenever there was no wind stirring, we were sure to get a shower." Great fires are comparatively rare in this country, and I have never seen the formation even of cloud here from such a cause. However, I did once observe this phenomenon. Many years ago when sailing up the Mississippi near its mouth, in a clear and cool evening, after the subsiding of a "Norther," a great fire was burning among the reeds on its west bank. Above the dark smoke the true cumulus cloud was distinctly formed. Its bright and rounded form was beautifully brought out in the setting sun. No other clouds were visible around, and these were soon left behind as we ascended the river.

If we reflect on the matter it is difficult to conceive how clouds could be formed by means of fires during windy weather. The ascending columns could not be formed under such conditions, for the heated air would be rapidly swept off, and diluted with the mass of air rushing past. This may be illustrated by other examples better known than the formation of the cumulus. Volcanoes are well known to produce at times clouds as well as rains. But all the vapour or heat that Vesuvius could emit during an active eruption would not produce rains when a strong and dry north-west wind was blowing across its top. So also the beautiful and true cumulus cloud that so often hovers over the Falls of Niagara is only seen in calm weather. Under favourable atmospheric conditions I have lately been informed by Dr. Henry Washington that the Niagara cloud sometimes gives rise to rains and electrical phenomena. The true inference seems to be that great fires will not produce rain, excepting "the air is calm, and the dew-point high." ROBERT RUSSELL

Pilmuir, Leven, Fifeshire,

A BILL TO ESTABLISH THE METRIC SYSTEM OF WEIGHTS AND MEASURES

THE following Bill, prepared and brought in by Mr. J. B. Smith, Sir Charles Adderley, Sir Thomas Bazley, Mr. Graves, Mr. Baines, Mr. Albert Pell, Mr. Muntz, and Mr. Dalglish, has been ordered to be printed by the House of Commons:—

Whereas it is desirable that the weights and measures of the United Kingdom should be decimalised, and made to correspond with those of other countries.

And whereas the use of metric weights and measures is now legal, but no provision has been made for procuring the standards of said metric weights and measures, and for verifying and stamping those in use under the said Act.

Be it enacted by the Queen's most excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal, and Commons in this present Parliament assembled, and by the authority of the same as follows:—

1. From and after the expiration of ( ) years after the passing of this Act, the length of the metre to be prepared under the authority of the Privy Council for Trade, verified by comparison with the original standard in Paris, having the words and figures "Standard Metre, 1871," engraved upon it, and kept in the custody of the Warden of the Standards, shall be and is hereby declared to be the unit or only standard measure of lineal extension, wherefrom or whereby all other measures of extension whatsoever, whether the same be lineal, superficial or of capacity, shall be derived, computed, and ascertained, and all such measures shall be taken in decimal multiples or decimal parts of their respective units.

2. The unit of the measure of surface shall be the square of ten metres, which shall be and is hereby denominated the "are."

3. The unit of the measure of capacity, as well for liquids as for dry goods, shall be the cube of a tenth of the metre, and the same shall be and is hereby denominated the "litre."

4. The unit of weight shall be and is hereby denominated the "gram." A thousand grams shall be and is hereby denominated the "kilogram." A standard of the kilogram shall be prepared under the authority of the Privy Council for Trade, verified by comparison with the original standards in Paris, and have the words "Standard Kilogram, 1871," engraved upon it, and the same shall be kept in the custody of the Warden of the Standards.

5. For the more convenient use of metric weights and measures, it shall be lawful to take the double and the half of all the said units, and their decimal multiples and decimal parts.

6. The said weights and measures hereby established shall be and are hereby denominated the standard metric weights and measures, as shown in the table hereto annexed.

7. Copies and models of the same standard metre and kilogram shall be sent to the Lord Mayors of London and Dublin, to the Lord Provost of Edinburgh, and to all counties, shires, stewartries, ridings, divisions, cities, towns, liberties and places in which by law copies and models of the standard imperial weights and measures are required to be kept, and to such other places and persons as the President of the Committee of the Privy Council for Trade may from time to time direct.

8. All judges, magistrates and other person or persons who now are or shall hereafter be authorised by law to order or provide copies of the present imperial standard weights and measures, shall at all times hereafter have like power and authority in every respect to order and provide copies of the standard metric weights and measures, and to charge the expenses thereof upon the fund or funds, money or moneys, that would have been liable in case it had been copies of imperial weights and measures that had been ordered or provided.

9. All and every the provisions and provision which are by law in force with respect to the inspection, verification, reverification, stamping, counterfeiting and modes of conviction, with the penalty or penalties relating thereto, of the present imperial standard weights and measures, shall apply to and be in force with regard to the standard metric weights and measures in every respect as if the said standard metric weights and measures were comprised in and designated by the imperial weights and measures in the Acts relating to such inspection, verification, reverification, stamping, counterfeiting and modes of conviction, and the penalty or penalties relating thereto as aforesaid.

10. From and after the expiration of ( ) years from the passing of this Act, the imperial and all local or customary weights and measures shall be abolished, and every person who shall sell by any denomination of weights or measures other than those of the standard metric weights and measures, or such decimal multiples or decimal parts thereof as are authorised by this Act, shall, on conviction, be liable to a penalty not exceeding the sum of 40*s.* for every such sale.

11. From and after the expiration of ( ) years after the passing of this Act, if any person or persons shall print, or if the clerk of any market or other person shall make any return, price list, price current, or any journal or other paper containing price list or price current in which the denomination of weights and measures quoted or referred to shall denote or imply a greater or less weight or measure than is denoted or implied by the same denomination of the metric weights and measures under and according to the provisions of this Act, such person or persons or clerk of the market shall forfeit and pay any sum not exceeding 10*s.* for every copy of every such return, price list, price current, journal, or other paper which he or they shall publish.

12. As soon as conveniently may be after the passing of this Act, accurate tables shall be prepared and published, under the authority of the Committee of Privy Council for Trade, showing the proportions between the imperial weights and measures heretofore in use and the standard metric weights and measures hereby established, with such other conversions of weights and measures as the said Committee of the Privy Council for Trade may deem necessary, and after the publication of such tables all future payments to be made shall be regulated according to such tables.

13. And whereas the weights and measures by which the rates and duties of the customs and excise and other Her Majesty's revenue have been heretofore collected, are different from the metric weights and measures directed by this Act to be used: It is hereby enacted, that so soon as conveniently may be after the passing of this Act, accurate tables shall be prepared and published under the direction of the said Committee of the Privy Council for Trade, in order that the several rates and duties of customs and excise, and other Her Majesty's revenue, may be adjusted and made payable according to the respective quantities of the standard metric weights and measures directed by this Act to be used, and that on the expiration of ( ) years after the passing of this Act, the several rates and duties thereafter to be collected by any of the officers of Her Majesty's customs or excise, or other Her Majesty's revenues, shall be collected and taken according to the calculations in the tables to be prepared as aforesaid.

14. From and after the passing of this Act, and until the use of the metric weights and measures shall be made compulsory, the said metric weights and measures shall be deemed and taken to be legal weights and measures, and as such may be used for all purposes whatsoever.

15. As soon as conveniently may be after the passing of this Act, the metric standards to be provided under this Act shall be placed in the custody of the Warden of the Standards, and the Committee of the Privy Council for Trade shall cause the metric weights and measures in use under the present Act to be verified and stamped in the same manner as the imperial weights and measures are now required to be.

16. From and after the passing of this Act the "Metric Weights and Measures Act, 1864," shall be and is hereby repealed.

FLOATING ISLANDS IN VICTORIA

GIPPSLAND is a province of Victoria. It is bounded by the Australian Alps on all sides except on the south, which the sea washes for over 100 miles. It may be called the Piedmont of Australia, rich fertile plains intersected by rivers flowing into a lake system extending all along the coast, and separated from the sea by a sandy narrow ridge, with one navigable opening. From a local paper, the *Gippsland Times*, I send the following description of "floating islands" on the lakes.

The alluvial deposit constantly brought down from the mountain ranges by the numerous rivers in this district, enables us to see a very decided process of land making continually going on, and thus teaches a useful lesson in geology.

AUSTRAL-ALPINE

Melbourne

"As one of the Gippsland Steam Navigation Company's steamers was recently crossing Lake Wellington, the man at the wheel suddenly observed land right in the track of the steamer, apparently only a short distance from the straits separating Lakes Wellington and Victoria. He called the captain's attention to the strange sight, and on coming up close, the land was discovered to be a small island, about thirty yards in length by twenty broad. It was covered with a rich coating of luxuriant grass; and small trees, tea tree, and bush shrubs appeared to be growing in profusion. The only occupants of this remarkable apparition were a few pigs, feeding away contentedly and apparently enjoying their novel journey by water. A second island of the same description, but much smaller, was noticed a little farther on, but this had evidently detached itself from the larger piece of land, or most probably had been separated by the rooting depredations of the porkers. From what portion of the main land this floating island came, is, of course, matter of conjecture, but it is known that a portion of the soil at Marley Point, on the southern shore of Lake Wellington, became detached recently, and floated miles across the lake with some twenty or thirty head of pigs aboard. As long as the wind drove it in that direction, the island drifted towards M'Lennan's Straits, but a change of wind brought it back again, after a three days' trip, within a mile of the spot from which it had broken away. We believe it is the opinion of the district surveyor, Mr. Dawson, that the area of the Roseneath run, west of Lake Wellington, has been increased some twenty or thirty acres by the addition of drift islands."

WILHELM von HAIDINGER

WILHELM VON HAIDINGER is no more. He died after some years of failing health, though the illness to which he finally succumbed on the 19th of March was a short one. Among his veteran contemporaries in the mineralogist's craft, such as Breithaupt, Karl F. Naumann, Gustav Rose, and Karl C. von Leonhard, he must have stood second on the ladder of time, the venerable Breithaupt being some four years his senior. His father, Karl Haidinger, was a mineralogist, and indeed was for several years Professor of Mining at Schemnitz. But, while Wilhelm was yet an infant, his father died at Vienna, where he had, in his latter days, filled a post in the Imperial Mint.

The young Haidinger seems in some sort to have inherited his father's taste for minerals, for he joined the class of Mohs at Gratz, where that distinguished mineralogist was giving a new impetus to the study of his science by popularising it in what was termed a natural history system of classification, and by a systematic method of discriminating the different species of minerals; and subsequently young Haidinger went to Freiberg to complete his training in Mining. Count Breunner, who came to England in 1822, and was made a Doctor in Civil Law at Oxford, invited the young mineralogist to accompany him. He embraced the offer, and they travelled together through England, and together reached Edinburgh, where the energetic and winning character of the young Austrian, fresh with the lore of the famous lecture-room at Gratz, at once made him friends in the Northern Athens, in the University of which capital Jameson had already made Minerals a fascinating study. Among the friends he there made was Mr. Allan, the wealthy banker, who during the next year invited young Haidinger to make a home of his house while employed in translating the Mineralogy of Mohs into English. So after returning to Vienna, he once more, in 1823, came to Edinburgh, and made Mr. Allan's house his head-quarters till 1827. He appears to have been a sort of tutor to Mr. Robert Allan, the eldest son of his generous friend; and with him he travelled during these four years through Cornwall, and then through Norway, Sweden, Denmark, Germany, Austria, Italy, and France. It was mainly during these travels that the famous collection, afterwards the property of Mr. Robert Greg, and now in the British Museum, was formed.

During these four years he brought out his translation of Mohs' treatise, and wrote several Mineralogical papers for the Wernerian Society and the Transactions of the Royal Society of Edinburgh. Subsequently he joined with his brothers in starting a porcelain manufactory at Elbogen near Carlsbad. Here he continued till 1840, still, however, bringing out from time to time memoirs on new minerals or new observations on minerals already known. The minerals Edingtonite, Sternbergite, Fergusonite, Herderite, Erinite, Picrosmine, Johannite, Botryogen, and Hartite, are among those he studied and described previous to and during this period.

In 1840 he returned to his native city, Vienna, to devote himself more exclusively to the scientific pursuits he loved. Thenceforward his memoirs will be found distributed at pretty regular intervals through the Sitzungsberichte of the Vienna Academy.

Among the subjects that he worked at during the next period of his life were the optical phenomena exhibited by crystals in regard to light and colour; more particularly those of pleiochroism. He invented, for the investigation of these, the Dichroiscope, a simple but useful little instrument, enabling an observer to examine and compare the different characters of the absorption exercised by a birefringent crystal on light traversing it, according as the plane of vibration of the light is parallel or perpendicular to any one of the principal sections of the crystal. The description of Hauerite, a new mineral, in fact, a manganese pyrites, was given in 1847; that of Kenngottite in 1857. The Haidinger brushes, a subjective phenomenon due to the eye itself, and observed in looking towards a window through a tourmaline or Nicol prism, was an illustration of the acuteness of his powers of observation. A compendious and valuable treatise on Mineralogy, brought out in 1845, to take the place of an earlier treatise, was also, during this period of his life, continually undergoing revision for new editions; while new investigations of minerals were also appearing under his name

From the moment of the foundation of the Geological Institute for the Empire in Vienna, Haidinger was the obvious man to lead that younger generation by whose labours the new Institute was to be reared and supported. So he was its Director until some two or three years ago, when he retired from the position he had filled so well, with a Ritter's rank and a well-earned pension.

For the last twelve years of his life he had given his attention, almost to the exclusion of other scientific inquiry, to the subject of meteorites. He laboured indefatigably almost to the last in collecting specimens from any new falls of meteorites reported in any portion of the globe, that they might be added to the noble collection in the Imperial Museum; and he was always at work at the interpretation of the strange phenomena witnessed by those who have described the fall of meteorites in any language or country.

Such is a rapid review of the main features in the life of a man who seems always to have been at work; whose pen was one of the readiest and busiest; whose nature was ever genial and generous; and who, at the age of seventy-seven, has finished an honourable life's work, and leaves behind him a name which Austria may cherish as that of one of her illustrious sons, and which many an Austrian and many a foreigner will remember with warm respect; while those who enjoyed nearer relations with Wilhelm von Haidinger will assuredly ever remember him with affectionate regard.

N. S. M.

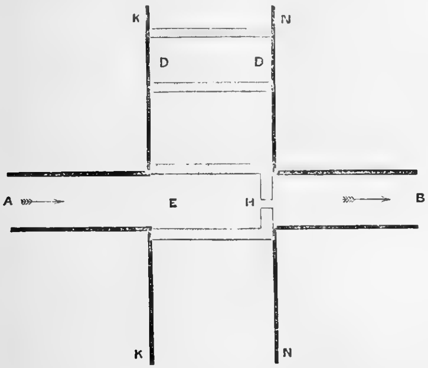
A TUBULAR POSTAL SERVICE

SOME large iron pipes have just been laid from the General Post Office to the Branch Office at Charing Cross, through which pipes packages of letters are blown in either direction at will, by compressed air. These tubes are to be extended from Charing Cross to the Houses of Parliament; and when the total expenses of laying pipes and of transmitting small packages through them is known by experience, very possibly the system may be extended, and letters intended for quick delivery may be sent by this method at a moderate charge.

This plan of sending messages through pipes for short distances has been employed in the City for many years in connection with the late Electric and International Telegraph Company. Seventeen or eighteen years ago, Mr. Latimer Clark laid down tubes from the Central Office of the Company in Lothbury to the Telegraph offices in Cornhill and Mincing Lane. By means of a steam-engine which worked a great air-pump, messages enclosed in small gutta-percha carriers, each somewhat resembling a sausage in shape and size, were drawn from Cornhill and Mincing Lane to Lothbury. Additional and smaller pipes were afterwards laid down by him, so that the vacuum could be applied to the further ends of the carrying pipes, in order that messages might be sent in the opposite direction also. They were then easily transmitted to and from Cornhill, but the Mincing Lane station being two-thirds of a mile off, it was found that the friction of the air in the pipes was too great, so that carriers could be sent in one direction only, namely, from Mincing Lane to Lothbury. Some years later, when Mr. C. F. Varley became engineer to the International Telegraph

Company, he employed compressed air to drive carriers to out-stations, and a vacuum to bring them back again. When a vacuum is employed, the carriers are driven by the ordinary atmospheric pressure only of fifteen pounds to the square inch, but when condensed air is employed, almost any pressure may be applied, so that the carriers can be driven with enormous velocity. He also substituted felt for gutta-percha carriers, since the latter were sometimes partially melted by the heat occasioned by friction, and coated the insides of the pipes with sticky matter. Further, he designed some pneumatic valves; the carriers, on arriving at the end of their journey, were made to strike against a brass button, the motion of the button set a valve to work, the valve opened the door of the chamber at the end of the pipe, the carrier then fell out, and dropped down on the table below. Thus the carriers were made to let themselves out when they arrived at the end of their journey, by which plan much hand labour on the part of assistants was saved. These improvements worked well, and are working well at the present time. Seven or eight City telegraph stations have been thus pneumatically connected for many years.

But a further improvement in the system has been made within the past year or two by Mr. C. W. Siemens. He lays down the pipes in circuits, and has pressure in the rear, and a vacuum in front of each carrier, so that as the



motive forces all act in one direction, there may be several carriers flying through the tubes at the same time. If these carriers were not stopped anywhere, they would all find their way back to the central station. He has invented also a "shunt," whereby any intermediate station can stop its own carrier, and pick it out of the tube without interfering with the motion of other carriers which may be flying through other parts of the circuit. Suppose the carriers to be three minutes apart in point of time, and that five stations are on the circuit, each station knows at what time its own carrier is due, so is able to take it out without interfering with other carriers. If the carriers be not sent at regular intervals of time, the receiving station can be told when its carrier is started, by telegraph. The plan of picking out the carriers is simple, and the principle may be explained by the aid of the accompanying diagram. A B is the main tube, and the direction taken by the carriers is denoted by the arrows; K K and N N are metal plates, between which the two short tubes D D and E H slide in an air-tight manner. These two short tubes are attached to a lever joint. When the assistant does not wish to intercept a carrier, the tube D D is left in the place occupied by the tube E H in the cut, and D D being open at both ends, carriers pass through it without interception. Upon sliding E H into the gap in the main tube, however, the carrier is stopped by it. It is brought to a standstill very gently, because it compresses some air in front of itself, which air issues with restricted freedom through the hole H; thus the carrier makes for itself an air-cushion to break the violence of the blow. When the carrier is caught, the tube D D is brought into the line of the main tube, after which an air-tight door in the side of E H is opened, and the captured carrier, with its messages, is taken out.

For short distances to and from telegraph stations near the Bank and the Post Office, the pneumatic tubes are from one-and-a-half to two and-a-half inches in diameter; they vary in diameter according to distance. But the one large Siemen's circuit at present laid in London goes from Telegraph Street to Charing Cross and back, the General Post Office and the Temple Bar Office being the intermediate stations; this pipe is three inches in internal diameter. The carriers travel at the rate of about a mile in three minutes, but the rate varies with the pressure.

It may be asked why these pneumatic tubes are useful in connection with telegraphic offices? The fact is, that there are many disadvantages in sending messages very short distances by the electric telegraph. Suppose one telegraphic wire be suspended between two stations half a mile apart, and another be suspended between two stations three hundred miles apart; let thirty messages be received all at once for transmission over each of these two wires, it is plain that some of these messages will have to wait half an hour before their turn comes to be signalled over the wire. The public will not complain of a delay of half an hour in the delivery of a message in a town three hundred miles off, but they would make a great outcry if a message took half an hour to go half a mile by the electric telegraph. Therefore, it is the simplest and most expeditious plan for the central telegraph station in a great city to blow the messages bodily through tubes, to branch stations not far off; the plan saves time and saves labour. Complaints published in the newspapers about delays in telegraphic messages, refer for the most part to telegrams sent from one part of London to another, and the delays are often caused by the pressure of a sudden influx of work upon particular wires. WILLIAM H. HARRISON

NOTES

WE learn that the volume containing the various observations of the recent total eclipse will be edited by the Astronomer Royal.

IT is stated that Mr. Abel, Prof. Ramsay, and Mr. Huggins, have been invited to lecture this year to the members of the British Association at the forthcoming meeting at Edinburgh.

THE meeting of the Royal Colonial Institute on Monday is likely to have a practical result. The paper read was by Mr. Hyde Clark on the "Appointment of a Reporter on Trade Products for the Colonial Office." After an interesting discussion the President, Lord Bury, M.P., on the part of the Council, proposed that a Committee should be named to apply to the Secretary of State for the Colonies for such a department, and for the provision of a Colonial Museum on the same l a is as the department provided at the India Office for India.

AT the last anniversary meeting of the Chemical Society it numbered 551 ordinary members and 36 foreign members. Six of the former have withdrawn from the Society,—on the other hand forty-two new members have been elected into the Society. It has lost five ordinary members by death, viz., Mr. George Jolley, Dr. W. A. Miller, Dr. Aug. Matthiessen, Dr. J. S. Muspratt, and Mr. W. W. Rouch; and the deaths must also be recorded of two foreign members, viz., Prof. Gustav Magnus and Prof. Weltzien. The election of the president, the officers, and the other members of Council for the ensuing year was then proceeded with, and the following is the list of the gentlemen elected :—President : Frankland, E., D.C.L., F.R.S. Vice-Presidents, who have filled the office of President : Brodie, Sir B. C., F.R.S. ; De la Rue, Warren, Ph.D., F.R.S. ; Hofmann, A. W., D.C.L., F.R.S. ; Playfair, Lyon, Ph.D., C.B., F.R.S. ; Williamson, A. W., Ph.D., F.R.S. ; Yorke, Col. P., F.R.S. Vice-Presidents : Debus, H., Ph.D., F.R.S. ; ilbert, J. H., Ph.D., F.R.S. ; Noad, H. M., Ph.D., F.R.S. ; Odling, W., M.B., F.R.S. ; Redwood, T., Ph.D. ; Stenhouse, J., Ph.D., F.R.S. Secretaries : Harcourt, A. Vernon, M.A., F.R.S. ; Perkin, W. H., F.R.S. Foreign Secretary : Müller, H., Ph.D., F.R.S. Treasurer : Abel, F.A., F.R.S. Atkinson, E., Ph.D. ; Bassett, H. ; Bloxam, C. L. ; Dupré, A., Ph.D. ; Field, F., F.R.S. ; Holzmann, M., Ph.D. ; M'Leod, H. ; Mills, E. J., D.Sc. ; Roscoe, H. E., Ph.D., F.R.S. ; Russell, W. J., Ph.D. ; Smith, R. Angus, Ph.D., F.R.S. ; Voelcker A., Ph.D., F.R.S.

DR. GEORGE BURROWS, F.R.S., Physician Extraordinary to the Queen, has been elected President of the Royal College of Physicians, in succession to Sir James Alderson.

A THIRD (revised) edition is now in the press of Mr. Darwin's "Descent of Man."

MR. JAMES CROLL calls our attention (*à propos* of our notice of his paper "On the Cause of the Motion of Glaciers," No. 68, p. 309) to the fact that he does not conclude the age of the sedimentary rocks to be 1,036,800,000 years, but *assumes* the period—for reasons stated on a former occasion—to be only 100,000,000 years. The drift of the paper was to point out a "new method" of determining the (mean) thicknes of the sedimentary rocks. The method leads to the conclusion that their thickness cannot be much over 2,500 feet !

DR. HOOKER has just started on a botanical expedition of eight or ten weeks into the interior of Morocco, a hitherto almost untried field. He is accompanied by Mr. R. Ball and one of the gardeners from Kew to assist in collecting plants.

WE learn from the *Journal of Botany* that Dr. Karl Heinrich Schultz-Schultzenstein, of Berlin, one of the most eminent botanists in Germany, was found dead in his bed on the morning of March 23rd. He had been engaged at his desk till past midnight. The deceased, though in his seventy-third year, was remarkably active, and was lecturer on physiology, as well as on botany, in the University of Berlin, with which he had been connected since 1822.

THE Medical Scholarship for Women in Edinburgh University of the value of 50*l.* for three years, offered for competition by Mrs. Garrett Anderson, M.D., and two other ladies, has been gained by Miss Annie Barker, daughter of Dr. Barker of Alderhot. It was awarded according to the results of the preliminary examination in Arts in the University.

WE learn from Paris that M. W. De Fonvielle was sentenced to death by the insurgents in consequence of an article published in the *Times* of March 27. We have however had the satisfaction of receiving from him this week our usual budget of Paris news. The only men of science who have ranked with the insurgents are M. Le Français, a former teacher in an elementary public school, M. Jules Allix, inventor of a new system of orthography, M. Charles Emmanuel, who opposes the theory of the rotation of the earth from west to east ; Dr. Robault, a homœopathic practitioner, and M. Leroy, a foreman employed by Messrs. Hachette and Co. for reading for the press. A false rumour was circulated in the Quartier Latin that they were to send a delegate to take possession of the Observatory, the Ecole de Médecine, the Ecole de Droit, College de France, Institute, and Jardin des Plantes. All these establishments have, however, been left undisturbed in the hands of the scientific authorities.

LAST week the *Journal Officiel* of the insurgents printed the account of the sitting of the Institute. But "reactionary" papers having sharply commented on the piracy, the *Officiel* abstained from mentioning the sittings of that assembly. The students have to a man ranked amongst the defenders of order. Almost every educational establishment is closed during "the revenge of science" proclaimed by the Commune. Pupils of the Polytechnic School were sent home, lectures at the Sorbonne, College de France, and Conservatoire des Arts have been stopped. Libraries are closed, and no books are being published or selling in Paris. There is no question of reform as long as the rebels enjoy their rule, and the Garde Nationale their thirty sous a day.

THE Hunterian Professor of Comparative Anatomy at the Royal College of Surgeons concluded his course on the Characters and Modifications of the Teeth of Mammalia on Wednesday, the 29th ult. In the last lecture the methods of drawing inferences as to the affinities and habits of extinct animals from dental characters were illustrated by the much controverted case of *Thylacoleo carnifex* of Owen, an extinct Australian marsupial, known at present only by its skull and teeth. The animal is supposed by its original describer to have been one of the fellest and most destructive of predatory beasts, and to exemplify the simplest and most effective dental machinery for predatory life and carnivorous diet known in the Mammalian class, a proposition which Prof. Flower contested, showing by comparison with all the recent marsupials, that its affinities are with the existing diprotodont species (kangaroos, potaroos, and phalangers), none of which are purely predaceous and carnivorous, and that, therefore, there can be no reason for inferring that *Thylacoleo* had such habits, unless any special modifications of its teeth towards the carnivorous type could be indicated. This was, however, shown not to be the case, by comparison with all the various known truly predaceous carnivores, whether belonging to the placental or to the marsupial type of mammals. There are, therefore, no grounds for the assumption on which the name of the animal is based. But, on the other hand, neither can it, according to Prof. Flower, be classed among herbivores in the ordinary sense of the word ; and all arguments against its "herbivority" derived from the structure of its molar teeth have no bearing on the proof that it was lion-like in its habits, as there are numerous alternative suppositions. Indeed, the teeth of this remarkable animal are so highly specialised and unlike those of any actually existing species, that it is impossible from analogy with recent forms to deduce its mode of life with any certainty, its organisation having in all probability been in conformity with some surrounding conditions which have now passed away.

AT a meeting of the American Ethnological Society of New York, held in October 1869, a committee was appointed for the purpose of organising a new body upon the basis of the society just mentioned, to be entitled the Anthropological Institute of New York. This committee lately issued invitations to the members of the Ethnological Society, and others interested, to attend at the house of Mr. E. G. Squier on the 19th of March, in order to complete the proposed arrangements by adopting a constitution and by-laws, to be formally presented to the meeting. In the present interest which attaches to studies relating to the past and present history of mankind and the development of civilisation, it is much to be hoped that this new society will establish itself on a firm foundation in New York, and carry out the mission projected for it by its founders.

FOR some years Dr. Burmeister, an eminent German naturalist and physicist, from Halle, has resided in Buenos Ayres, in charge of the National Museum in that city, and by his nvestigations and publications concerning specimens belonging to the Museum has given to it a great reputation. Quite recently, as we learn from *Harper's Weekly*, a murderous attack was made upon him by one of his servants, which was happily frustrated; but the newspaper comments upon the transaction developed the existence of so much animosity or jealousy toward foreigners on the part of the people that the doctor has finally determined to resign his position and return to Germany. Dr. Sarmiento, the President of the Republic, it is said, has endeavoured to change this determination, but apparently without effect. In parting with Dr. Burmeister, Buenos Ayres will lose one who has given to the country that position in science through his writings that Dr. Sarmiento has in literature, and his loss will not easily be made good. It is an interesting fact that both the National Museums of Chili and of the Argentine Republic are presided over by German naturalists, the director of the latter being Dr. R. L. Phillippi, well known in the scientific community.

IN June next Professor Birkett will commence his course of lectures on the Nature and Treatment of New Growths, at the Royal College of Surgeons, on the conclusion of which Mr. Hulke will deliver three lectures on the Minute Anatomy of the Eye.

WE learn from the *British Medical Journal* that Dr. E. Klein of Vienna has been appointed Assistant Professor in the new laboratory in connection with the Brown Trust for Experimental Pathology, which is about to be erected in London. Dr. Klein has been Professor Stricker's assistant for several years, and has contributed much to that author's "Handbook of Histology," now being published in English by the New Sydenham Society. By this change, Austria will lose and this country gain one of the most promising of young histologists. As an investigator and teacher of the structure of tissues, Dr. Klein has been for several years held in much esteem in Vienna.

THE following are the arrangements for the Lectures at the Royal Institution of Great Britain after Easter, 1871:—On Tuesdays, April 18 and 25, and May 2, William Pengelly, F.R.S., will deliver three lectures "On the Geology of Devonshire, especially of the New Red Sandstone." On May 9 and 16, Charles Brooke, F.R.S., will lecture "On Force and Energy." On May 23 and 30, and June 6, the Rev. Professor Haughton, M.D., F.R.S., will lecture "On the Principle of Least Action in Nature, Illustrated by Animal Mechanics." On Thursdays, April 20 to June 8, Professor Tyndall, LL.D., F.R.S., wil deliver eight lectures "On Sound;" and on Saturdays, April 22 to June 10, J. N. Lockyer, F.R.S., will deliver eight lectures "On Astronomy." The lecture hour is three o'clock. The following are the probable arrangements for the Friday evenings after Easter, 1871, to which members and their friends only are admitted:—April 21, Professor Blackie, F.R.S.E., "On the Pre-Socratic Philosophy." April 28, Professor Odling, F.R.S. May 5, W. R. S. Ralston, M.A., Trinity College, Cambridge, "On Russian Folk-Lore." May 12, Professor Huxley, F.R.S. May 19, Colonel Jervois, R.E., C.B., Secretary of the Defence Committee, and Deputy Director of Fortifications, "On the Defence of the United Kingdom." May 26, Sir J. Lubbock, Bart, M.P., F.R.S., "On Relationships." June 2, Professor Thomas Andrews, F.R.S., Principal of Queen's College, Belfast, "On the Gaseous and Liquid States of Matter." June 9, Professor Tyndall, LL.D., F.R.S.

PROF. WINCHELL, director of the Geological Survey of Michigan, has lately presented a report of the progress of the survey from its inauguration, May 1869, to November 1870. He sketches an outline of the nature and extent of the researches he proposes in connection with the investigations, and expresses a desire for sufficient appropriations to enable him to complete his work in the shortest possible time, two years being suggested as sufficient with proper means. His plan includes, in addition to pure geology and mineralogy, such subjects as palæontology, climatology, natural history, ethnology, &c. The sum of 61,300 dols. is asked for by the Professor for the purpose of completing his field work, as well as of preparing the necessary maps and illustrations for his report.

WE have information of the departure of M. Miclucho Maclay, of Russia, in the Russian steamer *Witiaz*, for a seven or eight years' cruise in the Pacific—the first two of which are to be expended in the investigation of the island of New Guinea. This region, as is well known, abounds in objects of natural history of the greatest interest, although comparatively little, so far, is known of its features in detail.

THE Royal Belgian Academy of Science, Letters, and the Fine Arts has just issued its thirty-seventh *Annuaire*, containing a historical sketch of the Academy, and biographical sketches of the following members who died during the year:—François Joseph Navez, painter, with a list of his works and pupils; Edward Ducpetiaux, political economist and prison reformer; Charles-Fréd.-Phil. von Martius, the celebrated botanist; Edouard Gerhard, philologist and archæologist; Prudens Van Duyse, poet; and Charles Aug. de Bériot, composer.

THE new explosive dualin has been used in the blastings required for the great Hoosac tunnel in the United States. Over 1,000lb. have been exploded since December 1, and it appears to possess the full strength of nitro-glycerin, besides being perfectly safe from any ordinary blaster to handle. It will not explode by concussion, and can be tamped as hard as powder with perfect safety. There seems no reason why it will not eventually entirely supersede common powder for all blasting purposes.

THE *Scientific American* announces a substitute for lime in the lime-light of the oxyhydrogen jet. It appears that a prism cut out of the mineral dolomite will emit a light as powerful if not superior to the calcium light. The dolomite is made up of nearly equal parts of the carbonate of lime and magnesia, and the combination of these two earths produces effects superior to what can be obtained from either of them alone. The light is said to be suited for photographic purposes, especially for copying pictures. As dolomite is an abundant rock, its application for purposes of light may prove of peculiar value.

THE report of the Manchester Field Naturalists' Society for 1870 has, according to the Secretary, "little to say except that the year's proceedings have been marked by smoothness and success, with no particular incidents to give it distinction above preceding years, and certainly without any of an infelicitous kind." The meetings have been well attended; there has been a considerable entry of new members; and the Treasurer's report is satisfactory. The report is taken up with brief *résumés* of the proceedings at each meeting, and a summary is given of a useful paper by Mr. R. B. Smart "On the Variation of Species" in the vegetable kingdom. We much regret that, from a society numbering its members by hundreds, we cannot obtain a proportionate amount of work; indeed many of the smaller bodies put the Field clubs of our large towns to shame in this respect. Mr. Grindon's "Flora of Manchester" is not only out of date, but also out of print; and a complete fauna and flora of the district would be both useful to naturalists and creditable to the society. Surely among so many members some may be found both able and willing to undertake such a work. We observe that the Secretary, in the present report, speaks of plants by their English names, some of which are of his own invention. As their scientific equivalents are omitted we are left in the dark as to some of them; "dimplewort" is, we believe, *Cotyledon umbilicus*, but "blushwort" baffles our ingenuity. The President for 1871 is Mr. Thomas Turner, F.L.S., and Mr. Grindon continues to act as Secretary, THE time for the trial of machines for separating the fibres of the Rhea plant which are to be sent in by competition for the Indian Government prize of 5,000*l.*, has been postponed till April 1872. It is requested that notice of intention to compete be given before May of this year. Arrangements have been made for supplying some of the plant to intending competitors.

THE FIRST GERMAN NORTH POLE EXPEDITION

A NUMBER of Petermann's "Mittheilungen" published in January 1871, consists of an account of the first German North Pole Expedition by Captain Koldewy and Dr. A. Petermann. The vessel in which this expedition was undertaken was the *Germania*, a cutter of only eighty tons burden. Twelve persons sailed in her, Captain Koldewey, the commander of the party and joint author of the present memoir, R. Hildebrant, chief mate, and ten sailors. They started from Bergen May 24, 1868, the Swedish expedition sailing about the same time in a steamer. The voyage extended over four months. Dr. Petermann considers that the only practicable routes to the North Pole are either through Behring's Straits or the sea between Greenland and Spitzbergen. The latter was attempted by the Expedition.

The year turned out to be a most unfavourable one, the sea being more than usually obstructed with ice. After vainly attempting to reach the east coast of Greenland, the *Germania* crossed over to Spitzbergen, but was stopped by pack-ice. Greenland was again visited with a like result; but on a second trial of the Spitzbergen route a fortunate break in the ice occurred, and on September 14, lat. 81°·5 was reached, this being the highest point ever yet attained by a ship, although with sledges 82°·45 was reached by Parry in 1827. The east coast of Spitzbergen was visited by means of the straits (Hinlopen Strasse) which separate the smaller northern portion of this group of islands from the larger southern portion. Here a new island was discovered, and the surrounding coast-line mapped. Dr. Petermann names the island William Island, and the straits which separate it from the mainland Bismark Straits; we also find on the map Augusta Bay and Cape Moltke. Dr. Petermann rejoices greatly that the Germans have thus at last left their mark on the map. He says that it has been very trying to him to have seen for the last thirty-two years in maps of all parts of the world containing new geographical discoveries no names but "Victoria," "Wellington," "Smith," "Jones," &c. Captain Koldewey describes the glaciers of Spitzbergen as differing from those of Switzerland in the following points:—They for the most part stretch right down into the sea, where they end in a perpendicular wall. The upper surface is somewhat polished and free from all roughness and steep ice blocks. Moreover in the glaciers examined at Augusta Bay and William Island there are no crevasses. Moraines are present, those of the great glacier in Augusta Bay consisting of limestone and basalt. The actual scientific results of the expedition are very small, owing to the badness of the weather. Some fragmentary monthly isothermals of sea temperature have been constructed by Dr. Petermann from the observations made during the voyage, and are marked on the two maps which accompany the memoir. Captain Koldewey considers that the route by the East coast of Greenland is the one which should be attempted by future expeditions. The route north of Spitzbergen is impracticable, because a branch of the Gulf Stream here meets directly the cold polar current, and a barrier of ice is the result. For further exploration he advises the employment of a schooner rigged vessel of from 150 to 200 tons, with auxiliary steam power.

REPORT ON DEEP-SEA RESEARCHES

Carried on during the months of July, August, and September, 1870, in H.M. Surveying Ship "Porcupine."

BY W. B. CARPENTER, M.D., F.R.S., AND J. GWYN JEFFREYS, F.R.S.

(*Concluded from p.* 417.)

WE commenced our observations on the morning of Oct. 1 at the point of greatest depth (Station 65). The temperature of the surface at 6 A.M. was only 63°, which was at least eight degrees lower than the average temperature at that hour within the Mediterranean. The bottom temperature at 198 fathoms was 54°·5; and the specific gravity of the bottom water was 1028·2. The coincidence both in temperature and specific gravity with the bottom-water at Station 64 was thus very close. The place of the ship having been determined by angles taken with the shore, the rate of the surface-movement was tested as on former occasions; and was found to be 1·277 mile per hour, its direction being E. ½ S. The "current drag" was then sunk to 150 fathoms,—the greatest depth at which it was thought safe to use it; and the boat from which it was suspended moved E. ¾ N. at the rate of 0·840 mile per hour. This observation indicated a very considerable retardation in the rate of *in*-flow; but gave no evidence of an *out*-flow. It did not, however, negative the inference deducible from the temperature, and still more from the specific gravity of the water beneath, that an out-flow takes place in that lowest stratum which we could not test by the "current drag."

We then steamed across the deep channel towards the Spanish side; and passing a bank of 45 fathoms which rises near its middle, we sounded again at Station 66, about six miles to the northward of Station 65. The surface-temperature at 9 A.M. was here found to have risen to 69°; and since not more than half this increase could be attributed, according to our experience elsewhere, to the increase of direct solar radiation at this period of the day, the cause of the additional elevation has to be sought elsewhere. The length of sounding-line run out was 147 fathoms; but on attempting to reel it in, the lead was found to have fixed itself between rocks; and all Capt. Calver's skill in the management of his ship proved inadequate to free it. As we were thus anchored by our sounding-line, it was requisite to set ourselves free, by putting a breaking strain upon it; and we thus lost, with the lead, one of our water-bottles, and a pair of thermometers, one of which was specially valued by us as having been used throughout the *Porcupine* Expedition of 1869, in which the temperature soundings had proved of peculiar importance. The "current-drag" was here let down to 100 fathoms; and the boat from which it was suspended moved along in the direction of the surface-current, and at the rate of 1·280 mile per hour, which was almost precisely that of the surface-current in the previous observation.

Deeming it important to obtain the temperature and specific gravity of the bottom-water on the Spanish side of the deeper portion of the channel, we slightly shifted our ground, and again let down our lead, with thermometers and water-bottle, at Station 67, where the depth proved to be 188 fathoms. On beginning to reel in the line, we found the lead to have anchored as before, and for some time feared that we should sustain a second loss of the water-bottle and thermometers attached to it. The means taken by Captain Calver for its extrication, however, proved on this occasion successful; and we had the satisfaction of seeing the whole apparatus safely brought up,—the lead bearing evident marks of having been jammed between rocks and then violently strained. The temperature of the bottom proved to be 55°·3, that of the surface being 73°; and the specific gravity of the bottom-water was 1028·1, that of the surface being 1026·8. Here again, therefore, the evidence afforded by the temperature and specific gravity of the bottom-water was conclusive as to its Mediterranean character. Its density corresponded rather with that of the bottom-water, than with that of the intermediate stratum, at the opposite end of the Strait; but the more rapid westerly motion of the latter would seem to indicate that the water which here flows over the "ridge" is derived from it, rather than from the deeper layer, and that its diminution in density is due to the dilution it sustains in its course. In either case, the denser Mediterranean water discharged by this under-current must flow up-hill; but the incline is so gradual that a very small force, if constantly sustained, would suffice to produce the elevation needed to carry it over the ridge.

Whilst we were prosecuting these inquiries, our attention was attracted by the long chains of aggregate salpæ which were floating close to the ship near the surface of the very calm sea. We were able to collect four or five different species of these, and to submit them during life to microscopic examination. The reversal of the direction of the circulation took place in all at more regular intervals than we have usually found to be the case in the compound ascidians; and we were able to distinguish an unmistakable rudimentary eye, which had not, we believe, been previously noticed. We hope to be able hereafter, by the detailed study of these specimens, to make some additions to the knowledge previously acquired of this very interesting group. As the nature of the bottom put it out of the question to attempt to dredge on this ridge, our only means of investigating its zoology lay in the use of the "hempen tangles." A "sweep" taken with these brought up a few echinoderms and polyzoa of no special interest.

We now took our final leave of the Mediterranean basin with mingled feelings of disappointment and satisfaction. The zoological results of our cruise had been by no means equal to our expectations; but, on the other hand, we could console ourselves with the belief that our determination of the peculiar physical conditions of this great inland sea, and in particular our elucidation of the mystery of the Gibraltar current, would be fairly regarded as a success. And we venture to think that this will be admitted by such as may follow us through the discussion of general results, to which we shall presently proceed.

As Captain Calver considered himself bound not to make any unnecessary delay in returning homewards, and to take every advantage of the continuance of the fair weather and favourable breeze which we enjoyed during nearly the whole remainder of our voyage, we were reluctantly compelled to give up the idea of prosecuting any further researches in the Deep Sea; and devoted ourselves to the examination of the specimens previously collected, and to the correlation of our temperature and other results,—specially directing our attention, however, to the surface-temperature of the *embouchure* of the Strait, with the view of ascertaining whether a sudden *fall* would be observable on quitting it, corresponding to the *rise* which had been noticed on the outward voyage on entering it. This change proved to be very decided. As we kept along the southern coast of Portugal towards Cape St. Vincent, the surface-temperature averaged 73°·5. At 6 P.M. we were turning the corner of the Cape, and found the surface-temperature 72°·5. And at 8 P.M., when we were fairly in the Atlantic, we found that the surface-temperature had fallen to 69°, thus showing a difference of 4°·5. On the following day, when we were off Lisbon, the surface-temperature was 69°·5; and it gradually diminished as we proceeded northwards from that point. Although the season of the year led us to expect a rough passage across the Bay of Biscay, the weather continued remarkably fine until we reached the "Chops of the Channel," where we fell in with rather a fresh breeze; this did not interfere, however, with our anchoring at Cowes on the afternoon of the next day (October 8th), after an absence of just two months, during which a greater number of most important public events had occurred than had ever before been crowded within so short a period.

General Oceanic Circulation.—The difference as to level and density between two bodies of sea-water, which produces the vertical circulation in the Strait of Gibraltar and the Baltic Sound, may be brought about otherwise than by the excess of evaporation which maintains it in the one case, or by the continual dilution with fresh water which maintains it in the other. It may be easily shown that a constant and decided *difference of temperature* must have exactly the same effect. Let the Mediterranean basin be supposed to be filled with water of the same density as that of the Atlantic and up to the same level; and to be then cooled down below the freezing-point of fresh water by the withdrawal of solar heat, whilst the surface of the Atlantic continues to be heated as at present by the almost tropical sunshine of the Gibraltar summer. The cooling of the Mediterranean column, reducing its bulk without any diminution of weight, would at the same time lower its level and increase its density. An in-draught of Atlantic water must take place through the Strait to restore that level; but this in-draught would augment the weight of the column, giving it an excess above that of the column at the other end of the Strait; and to restore the equilibrium a portion of its deeper water must be forced out as an under-current towards the Atlantic, thus again reducing the surface-level of the Mediterranean. Now, so long as the warm Atlantic water which comes in to maintain that level is in its turn subjected to the same cooling, with consequent lowering of level and increase of density, so long would the vertical pressures of the two columns, which would be speedily restored to equilibrium if both basins were subjected to the same heat or the same cold, remain in a constant state of inequality; and so long, therefore, must this vertical circulation continue.

Now, the case thus put hypothetically has a real existence. For the Mediterranean, cooled down by the withdrawal of solar heat, let us substitute the Polar basin, and for the Atlantic, the Equatorial Ocean. The antagonistic conditions of temperature being constantly sustained, a constant interchange between polar and equatorial waters through the seas of the Temperate Zone must be the result. The reduction in the temperature of the Polar column must diminish its height whilst augmenting its density; and thus a flow of the upper stratum of equatorial water must take place towards the poles to maintain the level thus lowered. But when the column has been thus restored to an equality of height, it will possess such an excess of weight that its downward pressure must force out a portion of its deeper water; and thus an underflow of ice-cold water will be occasioned from the polar towards the equatorial areas.

The agency of polar cold will be exerted, not merely in reducing the bulk of the water exposed to it, and thereby at the same time *lowering its level* and *increasing its density*, but also in imparting a *downward movement* to each new surface-stratum as its temperature is reduced, whereby a continual in-draught will be occasioned from the warmer surface-stratum around. For the water thus newly brought under the same same cooling influence will descend in its turn; and thus, as the lowest stratum will be continually flowing off, a constant motion from above downwards will continue to take place in the entire column, so long as a fresh stratum is continually being exposed to the influence of surface-cold.

On the other hand, the agency of equatorial heat, though directly operating on only a thin film of surface-water, will gradually pump-up (so to speak) the polar water which has reached its area by creeping along the deepest parts of the intermediate oceanic basins. For since, as already shown, an in-draught of the upper stratum surrounding the polar basin must be continually going on, the place of the water thus removed must be supplied by water drawn from a still greater distance; and thus the movement will be propagated backwards, until it affects the upper stratum of the equatorial basin itself, which will flow off pole-wards, bearing with it a large measure of heat. The cold and dense polar water, as it flows in at the bottom of the equatorial column, will not directly take the place of that which has been draughted off from the surface; but this place will be filled by the rising of the whole superincumbent column, which, being warmer, is also lighter than the cold stratum beneath. Every new arrival from the poles will take its place below that which precedes it, since its temperature will have been less affected by contact with the warmer water above it. In this way an *ascending movement* will be imparted to the whole equatorial column, and in due course every portion of it will come under the influence of the surface-heat of the sun. This heat will of course raise the level of the equatorial column, without augmenting its absolute weight; and will thus add to the tendency of its surface-stratum to flow towards the lowered level of the polar area. But as the *super*-heating extends but a short way down, and as the temperature of the water beneath, down to the "stratum of intermixture," is very moderate, whilst the water below that stratum is almost as cold as that of the polar basin, it is evidently in the latter that the force which maintains this *vertical circulation* chiefly originates.

Here, then, we have a *vera causa* for a general oceanic circulation, which, being sustained only by the unequal distribution of solar heat, will be entirely independent of any peculiar distribution of land and water, provided always that this does not prevent the free communication between the polar and equatorial oceanic areas, at their depths as well as at their surface. That this agency has been so little recognised by physical geographers, we can only attribute to the prevalence of the erroneous idea of the uniform deep-water temperature of 39°, of which the temperature-observations made in our expeditions of 1868 and 1869 have shown the fallacy. Until it is clearly apprehended that *sea*-water becomes more and more dense as its temperature is reduced, and that it consequently continues to sink until it freezes, the immense motor power of polar cold cannot be apprehended. But when once this has been clearly recognised, it is seen that the application of *cold at the surface* is, in the case of sea-water, precisely equivalent as a moving force to the application of *heat at the bottom*, the motor power of which is universally admitted,—being practically utilised, in keeping up the circulation through the hot water warming apparatus now in general use.* The movement thus maintained would not, on the hypothesis, be a rapid one, but a gradual *creeping* flow; since the absence of limit would prevent the power which sustains it from acting as an *accelerating force*, as it would do if the equatorial and polar areas were connected only by a narrow channel, like the Atlantic Ocean and the Mediterranean Sea.

That the vertical circulation here advocated on *a priori* grounds, actually takes place in any mass of salt water of which one part is exposed to surface-cold and another to surface-heat, is capable of ready experimental proof:—Let a long narrow trough with glass sides be filled with salt water; and let heat be applied at one end (the equatorial) by means of a thick bar of metal laid along the surface, with a prolongation carried over the end of the trough into the flame of a spirit-lamp; whilst cold is applied at the other (the polar) by means of a freezing-mixture contained in a metallic box made to lie upon the surface, or (more simply) by means of a piece of ice wedged in between the sides of the trough. A circulation will immediately commence in the direction indicated by the theory; as may be readily shown by introducing some *blue* colouring liquid at the polar surface, and some *red* liquid at the equatorial surface. The blue liquid, as it is cooled, at once descends to the bottom, then travels slowly along until it reaches the equatorial end of the trough, then gradually rises towards the heated bar, and thence creeps along the surface back to the polar end. The red liquid first creeps along the surface towards the polar end; and then travels through exactly the same course as the blue had previously done.†

That such a vertical circulation really takes place in oceanic water, and that its influence in moderating the excessive cold of the polar areas and the excessive heat of the equatorial region is far more important than that of any surface-currents, seems to us a legitimate deduction from the facts stated in the Report of the "Porcupine" Expedition for 1869. For, on the one hand, it was shown that there is a general diffusion of an almost glacial temperature on the bottom of the deep ocean-basins, at depths exceeding 1000 fathoms, occupied by polar water, more or less diluted by admixture according to the length of the course it has had to travel; whilst between this stratum and that other stratum of warmer water which (on the hypothesis) is slowly moving pole-wards, there is a "stratum of intermixture," in which there is such a rapid change of temperature as might be expected from the relation of the upper and lower masses of water. This "stratum of intermixture" showed itself in a most marked manner in the Atlantic temperature-observations of the present expedition; the descent of the thermometer, which had been very slow with increase of depth between 100 and 800 fathoms, becoming suddenly augmented in rate; so that between 800 and 1000 fathoms it fell nine degrees, namely, from 49°·3 to 40°·3.

On the other hand, it was shown in the previous report that there is evidence of the slow pole-ward movement of a great upper stratum of oceanic water, carrying with it a warm temperature; which movement cannot be attributed to any such local influences as those which produce the Gulf-stream or any other currents put in motion by *surface*-action. Of such a movement, it was contended, we have a marked example in that north-easterly flow which conveys the warmth of southern latitudes to the west of Ireland and Scotland, the Orkney, Shetland, and Faroe islands, Iceland, Spitzbergen, and the polar basin generally. This flow, of whose existence conclusive evidence is derived from observations of the temperature of these regions, is commonly regarded as a prolongation of the Gulf-stream; and this view is maintained not only by Dr. Petermann,* who has recently collected and digested these observations with the greatest care, but also by Prof. Wyville Thomson,† as well as by Mr. Croll.‡ Having elsewhere fully stated our objections to this doctrine, and discussed the validity of the arguments adduced in support of it, § we shall here only record the conclusions which a careful examination of the present state of our knowledge of the subject has led us to form:—

I. That there is no evidence, either from the surface-temperature of the sea, or from the temperature of sea-board stations along the western coast of Southern Europe, that the climate of that region is ameliorated by a flow of ocean-water having a temperature higher than that of the latitude: the surface-temperature of the Mediterranean Sea, which is virtually excluded from all oceanic circulation, being higher than that of the eastern margin of the Atlantic in corresponding latitudes; and the climate of sea-board stations on the Mediterranean being warmer than that of stations corresponding to them in latitude on the Atlantic coast—and this not merely in summer, but also in winter. This oceanic region may therefore be designated the *neutral area*.

II. That the evidence of climatic amelioration increases in proportion as we pass northwards from the *neutral area*; becoming very decided at the Orkney, Shetland, and Faroe islands. But that, as was shown by the *Porcupine* temperature-soundings of 1869, the flow of warm water which produces this amelioration extends to a depth of at least 700 fathoms.

III. That this deep stratum of water can be shown, by the correspondence in the rate of its diminution of temperature with depth, to be derived from the neutral area to the south-west; where, as is shown by the *Porcupine* temperature-soundings of 1870, it is separated by a distinct "stratum of intermixture" from the deeper stratum that carries polar waters towards the equator.

IV. That the slow north-easterly movement of such a mass of water cannot, on any known hydrodynamical principles, be attributed to propulsive power derived from the Gulf-stream; the last distinctly traced edge of which is reduced to a stratum certainly *not exceeding* 50 fathoms in depth, and not improbably less.

V. That on the other hand, this slow pole-ward movement of the upper layer of the North Atlantic, down to the "stratum of intermixture," is exactly what might be expected to take place as the complement of the flow of glacial water from the polar to the equatorial area; the two movements constituting a general *vertical* oceanic circulation.

VI. That there is a strong probability that the quantity of water discharged by the Gulf-stream has been greatly over-estimated, in consequence of the rate of the surface-current having been assumed as the rate of movement through the whole sectional area, which is contrary to all analogy; whilst there is also a strong probability that there is a *reverse* undercurrent of *cold* water through the narrows, derived from the polar current, that is distincly traceable nearly to its mouth. The upper stratum of this southerly current comes to the surface between the Gulf-stream and the coast of the United States; whilst its deeper and colder stratum underlies the Gulf-stream itself. ||

VII. That there is a strong probability that the quantity of heat carried off by the water of the Gulf-stream has been greatly over-estimated; the temperature-soundings taken during the cruise of the *Porcupine* in the Mediterranean having shown that the very high temperature of the surface extends but a little way down; whilst the temperature observations in the Atlantic show that the descent into a cold stratum beneath may be very rapid. Hence the average of 65° assumed by Mr. Croll on the basis of observations made at considerable intervals of depth, is altogether unreliable.

VIII. That the most recent and trustworthy observations indicate that the edge of the Gulf-stream to the north-east of the banks of Newfoundland is so thinned out and broken up by interdigitation with polar currents, that its existence *as a con-*

* The only scientific writer who has even approached what appears to us the truth on this point, is Captain Maury, who has put forward the doctrine of a general interchange between the equator and the poles, resulting from a difference of specific gravity caused *inter alia* by difference of temperature. But as Mr. Croll remarks, "although Captain Maury has expounded his views on the cause of ocean currents at great length in the various editions of his work, yet it is somewhat difficult to discover what they really are. This arises from the general confused and sometimes contradictory nature of his hydrodynamical conceptions." See Mr. Croll's Paper "On the Physical Cause of Ocean Currents," in the "Philosophical Magazine" for October, 1870.

† This experiment has been exhibited, by the kindness of Prof. Odling, at the Royal Institution, and at the Royal Geographical Society.

‡ Memoir "On the Physical Cause of Ocean Currents," in "Phil. Mag., Oct. 1870.

§ Proceedings of the Royal Geographical Society, for Jan. 9, 1871.

|| That there is a slow southerly movement of Arctic water beneath the Gulf-stream, is indicated by the fact that icebergs have been seen moving southwards in direct opposition to its surface-flow; their deeply-immersed portions presenting a larger surface to the lower stratum than their upper part does to the more superficial layer, as in the case of our "current-drag." And similar evidence is afforded by the southward drift of the buoy which was attached to the Atlantic Cable of 1865, but which broke away from it, apparently carrying with it a great length of the wire rope by which it had been attached.

tinuous current beyond that region cannot be proved by observations, either of temperature or movement.

IX. That the Gulf-stream and other local currents put in motion by the trade-winds or other influences acting on the *surface* only, will have as *their* complement in a *horizontal* circulation return *surface* currents; and that the horizontal circulation of which the Atlantic Equatorial Current and the Gulf-stream constitute the first part is completed—so far as the Northern Hemisphere is concerned—partly by the direct return of one large section of the Gulf-stream into the Equatorial Current, and as to the other section, by the *superficial* polar currents which make their way southwards, the principal of them even reaching the commencement of the Gulf-stream.

In conclusion it may be added that the doctrine of a general vertical oceanic circulation is in remarkable accordance with the fact now placed beyond doubt by the concurrent evidence of a great number of observations, that whilst the density of oceanic water, which is lowest in the Polar area, progressively increases as we approach the Tropics, it again shows a decided reduction in the intertropical area. It has been thought that an explanation of this fact is to be found in the large amount of rainfall and of inflow of fresh water from great rivers in the intertropical region; but it is to be remembered that the surface evaporation also is there the most excessive, so that some more satisfactory account of the fact seems requisite. Such an explanation is afforded by the doctrine here advocated; the Polar water which flows towards the Equator along the bottom of the ocean basins, being there pumped up and brought to the surface.* And it is not a little confirmatory of the views advanced in this Report that in a recent elaborate discussion of the facts relating to the comparative density of oceanic water on different parts of the earth's surface, the doctrine of a general vertical circulation is advocated as affording the only feasible rationale of them.†

SCIENTIFIC SERIALS

THE *Zeitschrift fur Ethnologie* (1870 Heft III. and IV contains the following notices:—Orton's "Andes and the Amazon."—Waring's "Stone Monuments, Tumuli, &c.," "Manuscrit Troano," giving an account of the MS. in question, which is written in the Maya language; the reviewer calls this "surely the wildest production that ever saw the light with the sanction of an Imperial Government," though he admits that still wilder productions are published in his own country, now also under "Imperial government."—Benfey's "Gesch. de Sprachwissenschaft" is highly praised.—Burgen's "Temples of Satrunjaya," with forty-five photographs.—Hamy's "Paléontologie Humaine."

THE last part of the "Neues Jahrbuch für Mineralogie, Geologie," &c., published 1871, contains the following papers:—R. D. M. Verbeek on the Nummulites of the Borneo Rocks, with three plates illustrating new species, &c., one species, *N. Biaritzensis*, is also found in these beds, and extends through all the nummulitic formation from the Pyrenees to Borneo. He believes that this formation extends to Java and most of the islands of the East Indian Archipelago, but hitherto this formation has not been recognised.‡—Dr. R. Lincke on the Buntersandstein in Thüringen, which is the commencement of an elaborate monograph on these beds.—Dr. Alfred Stelzner on Quartz and Allied Minerals.—Adolph Pichler, Additions to the Mineralogy of the Tyrol; and, by the same author, Additions to the Palæontology of the Tyrol, and the usual mineralogical, geological, and palæontological notices.

OF the Transactions of the Natural History Society of Rhenish Prussia and Westphalia, including also the reports of the Society of Natural History and Medicine of the Lower Rhine, we have received the twenty-sixth volume, containing an account of the doings of the respective societies in the year 1869. The papers published by the first-mentioned society are well known to naturalists, and often of very great value. In the present volume we find the following:—"Contributions to the Rhenish Flora," by Dr. P. Wirtzen, including a discussion of the species of dog-roses, with the description of a so-called new species, *Rosa exilis*, a notice of *Asplenium Heufleri*, the description of a new plantain from Saarbruck, *Plantago Winteri*, a notice of the various forms of *Rubus tomentosus*, and of anomalies in other species of *Rubus*, and notices on the geographical distribution of certain plants; also, by the same author, a supplement to his manual of "The Flora of Rhenish Prussia; a paper "On the Height of the Water of the Rhine at Cologne from 1811-1867," by M. H. von Dechen; the continuation of Kaltenbach's valuable memoir on the German Phytophagous insects, in which the species feeding upon each species of plant are noticed, the plants being arranged in the alphabetical order of their botanical names, now reaching to the end of the letter S.; a contribution to the knowledge of the cryptogamous flora of the Saar district, by M. F. Winter, containing notices of Equisetaceæ, Lycopodiaceæ, and Ferns; and a paper, illustrated with three plates, "On the Fossil Echinodermata of North Germany," by Dr. C. Schlüter. In the last-mentioned paper, the author notices the described species of Jurassic and Cretaceous Echinoderms found in North Germany, and describes several new forms. The reports of the second society mentioned, which holds its meetings in Bonn, include an immense number of short notices of communications on almost all branches of science, but especially on Natural History and Chemistry; many of them are of considerable interest.

IN the March number of the *Journal of Anthropology* there is a careful anatomical description of the body of a negro by Dr. Kopernéki. Detailed measurements are added, together with the weights of the principal organs, and the diameter of more than twenty of the nerves. A remarkable feature in the case was the state of atrophy in which the supra-renal bodies were found; and if, in the absence of other fatal lesions, this may be assumed as the cause of death, there is here recorded a case of Addison's disease occurring in a negro. In the same journal is a translation of a review by Rütimeyer of Prof. Bischoff's work on the skulls of the anthropoid apes, in which both the text and the atlas of plates which accompanies it are severely criticised. Both the original pamphlet and the review have, however, lost much of the interest they possessed at the times of the publication, 1864 and 1868 respectively.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 30.—"Contributions to the History of Orcin.—No. 1. Nitro-substitution Compounds of the Orcins." By John Stenhouse, LL.D., F.R.S. The action of nitric acid upon orcin has been studied by several chemists, but with comparatively negative results. Schunck in this manner obtained a red resinous substance, which, by further treatment with the acid, was oxidised with oxalic acid; and in 1864 De Luynes found that orcin dissolved in cooled fuming nitric acid without evolution of nitrous fumes, and that the addition of water precipitated a red colouring matter; the long-continued action of the vapour of fuming nitric acid on powdered orcin likewise produced a red dye apparently identical with the above. These, however, are resinous uncrystallisable substances. Although under ordinary circumstances only resinous products are obtained by treating orcin with nitric acid, yet, when colourless orcin in fine powder is gradually added to strong nitric acid, cooled by a freezing mixture, it dissolves with a pale brown coloration, but without the slightest evolution of nitrous fumes. If this solution be now slowly dropped into concentrated sulphuric acid, cooled to -10° C., the mixture becomes yellow and pasty, from the formation of nitro-orcin, which is but slightly soluble in sulphuric acid. When this is poured into a considerable quantity of cold water, the nitro-body separates as a bright yellow crystalline powder, quite free from any admixture of resin. The crude nitro-orcin was collected, washed with a little cold water, and purified by one or two crystallisations from boiling water (40 parts). It was thus obtained in large yellow needles, which are readily soluble in hot water and but slightly in the cold; the addition of a strong acid precipitates almost the whole of the nitro-orcin from its cold aqueous solution. It is soluble in alcohol, very soluble in hot benzol, and crystallises out in great part on cooling; it is less soluble in ether, and but moderately so in bisulphide of carbon. It dyes the skin yellow, like picric acid, but is tasteless. It volatilises slightly at 100° C., melts at 162° C., and decomposes with slight explosion imme-

* That water of a *lower* should thus underlie water of a *higher* degree of salinity in travelling from the Pole to the Equator, is not difficult to account for, when the relative temperatures of the two strata are borne in mind

† Densité, Salière, et Courants de l'Océan Atlantique, par Lieut. B. Savy, Annales Hydrographiques, 1868, p. 620.

‡ It is not out of place to mention here that Baron Reichtofen has quite recently found this nummulitic formation in China; it is described in *Silliman's Journal* for February 1871. It has been found also in Japan.

diately afterwards. When heated with concentrated sulphuric acid it dissolves, forming a deep yellow solution, which deposits crystals on cooling, and is immediately precipitated by water. It dissolves in hot strong nitric acid with evolution of nitrous fumes and formation of oxalic acid. Like picric acid, when treated with calcium hypochlorite it yields chloropicrin at the ordinary temperature. Its aqueous solutions are coloured dark brown by ferric chloride, and completely precipitated by lead subacetate. The analysis of the substance dried at 100° C. was made with the following results derived from three experiments:—

	Theory		I.	III.	II.	Mean.
C_7 =	84	= 32·43	32·58	32·63	32·68	32·63
H_5 =	5	= 1·93	2·06	2·18	2·03	2·09
N_3 =	42	= 16·22	..	..	..	..
O_8 =	128	= 49·42	..	..	..	..
	259	100·00				

These results correspond to the formula $C_7 H_5 (NO_2)_3 O_2$ that of trinitro-orcin. It is a powerful acid, much resembling picric acid, but distinguished from the latter by the greater solubility of its salts. I propose, therefore, to call this new substance *trinitro-orcinic acid*. The preparation and composition of a large number of compounds of the acid were then detailed.

Geological Society, March 22.—Prof. John Morris, Vice-President, in the chair. Messrs. A. R. Selwyn, Director of the Geological Survey of Canada; J. Bridges Lee, the Rev. Thomas Robert Willacy, B.A., and James Putnam Kimball, Ph.D, New York, were elected Fellows of the Society. The following communications were read: 1. "On the Passage Beds in the neighbourhood of Woolhope, Herefordshire, and on the discovery of a new species of *Eurypterus*, and some new Land-plants in them." By the Rev. P. B. Brodie, M.A., F.G.S. The author described as the "passage-beds" between the Silurian and Old Red Sandstone formations near Woolhope, a series of shales and sandstones, which at Perton attain a thickness of about 17 feet. Here the section includes, in descending order:—(1) Thin-bedded sandstones; (2) Dark brownish shales; (3) Yellow sandstone; (4) Olive shales; (5) Thin bedded-sandstone; (6) Olive shales, similar to No. 4. At some localities vegetable remains (*Lycopodites*, and perhaps *Psilophyton*) occur in the olive shales, which also contain several Crustacean fossils, including *Pterygotus Banksii* and a new species of *Eurypterus*, named by Mr. Woodward *E. Brodiei*. Upon this species, Mr. Woodward presented a note supplementary to Mr. Brodie's paper. Mr. Duncan inquired whether any metamorphoses had been recognised among the Eurypteridæ, and, if so, whether the variation in the thoracic plates mentioned by Mr. Woodward might be connected with them. Mr. Woodward, in reply, remarked on the difficulty of distinguishing even the sexes in Eurypteridæ. The thoracic plate in the fossils resembled that of *Limulus*, and the variety might be connected with sex. In some *Slimoniæ* from Lesmahago the only difference to be found was in the thoracic plate, and it had been suggested that this was due to difference of sex. He had already suggested that the small *Pterygotus* and the great *Slimonia* might be only the male and female forms of the same species. On fragmentary remains it was, however, unsafe to attempt to base species; but he thought *Eurypterus Brodiei* was a well-marked species. Rev. E. Winwood inquired whether there was any evidence as to *Euypterus* being freshwater or marine. The chairman observed that the seeds from the passage-beds did not appear to him other than those of land-plants, and had been previously described by Dr. Hooker as spore-cases of Lycopodiaceæ.—2. On the Cliff-sections of the Tertiary Beds west of Dieppe in Normandy and at Newhaven in Sussex." By Mr. William Whitaker, F.G.S. The author gave details of the sections of the Tertiary beds at the above places, and noticed the occurrence of London clay. Below this formation at Dieppe is a mass of sand, the same as that of the "Oldhaven beds" in East Kent, but here less markedly divided from the clay above; and beneath this sand come the estuarine shelly clays, &c., of the Woolwich beds. In the older accounts of the Newhaven section a much less thickness of the Tertiary beds is chronicled than may now be seen; indeed the successive descriptions end upwards with higher and higher beds, owing to the destruction of the coast and the wearing back of the cliff into higher ground, the highest point seeming to have been at last reached. Here the Oldhaven sand is absent, but the Woolwich clays are in greater force; and the ditch of the new fort shows some very irregular masses of gravel more or less wedged into those clays. Both sections show the comparatively wide extent of like conditions to those of the Woolwich beds, of West Kent. The Chairman, in inviting discussion, called attention to the existence of Tertiary beds of similar character near Epernay and Rheims, and in other parts of France. Mr. Evans remarked on the bearing which this extension of soft, yielding strata had on the excavation of the Channel. The disturbances in the sands and clays might be due to the springs having formerly, owing to the distance of the sea and the river-valley not having been excavated, stood at a higher level, and having thus softened or even washed away, the bed beneath the gravels. Mr. Pattison mentioned that in all the combes along the French coast towards Tréport there were traces of soft Tertiary beds, possibly Thanet sands. Mr. Whitaker, in a reply to a question from the Chairman, stated that, to the best of his belief, the sandstones at Dieppe were not calciferous. The sands were above the Woolwich beds, and therefore not Thanet sands.—3. "On New Tree Ferns and other Fossils from the Devonian." By Prof. J. W. Dawson, L.L.D., F.R.S., F.G.S. The author referred to the numerous species of ferns known in the Upper and Middle Devonian of America, and to the fact that he had described several large petioles as probably belonging to arborescent species, and also two trunks covered with aërial roots, viz. *Psaronius erianus* and *P. textilis*. He also referred to *Caulopteris Peachii* of Salter as the only tree-fern known in the Devonian of Europe. He then described remains of four species of tree-ferns in collections communicated to him by Dr. Newberry of New York. The first of these, *Caulopteris Lockwoodi*, was found by the Rev. Mr. Lockwood at Gilboa, the locality of the Psaronites already mentioned, in rocks of the Chemung group. It is a fragment of a well-characterised stem, with parts of five petioles attached to it, and associated with remains of the leaves. It must have been entombed in an erect position, and is not improbably the upper part of one of the species of *Psanonius* from the same locality. The second species, *Caulopteris antiqua*, Newberry, is of much larger size, but less perfectly preserved. It is a flattened stem on a slab of marine limestone from the Corniferous formation in the lower part of the Middle Devonian (Erian) of Ohio. The third species, *Protopteris peregrina*, Newberry, is from the same formation with the last, and constitutes the first instance of the occurrence of the genus to which it belongs, below the Carboniferous. The specimens show the form and arrangement of the leaf-scars, the microscopic structure of the petioles, and also the arrangement of the aërial roots covering the lower part of the stem. The fourth species is a gigantic *Rhachiopteris*, or leaf-stalk, evidently belonging to a species quite distinct from either of the above and showing its minute structure. It is no less than four inches wide at the base. In the cellular tissue of this petiole are rounded grains similar to those regarded by Corda and Carruthers, in Carboniferous and Eocene specimens, as starch-granules. In addition to these species, the paper described a new *Næggerathia* (*N. gilboensis*), and noticed a remarkable specimen from Caithness, in the collection of Prof. Wyville Thomson, throwing light on the problematical *Lycopodites Vanuxemii* of America; also interesting specimens of *Psilophyton* and other genera seen by the writer in the collection of Mr. Peach of Edinburgh. Dr. Duncan doubted the desirability of basing generic and specific terms on imperfectly preserved and indistinct specimens, and pointed out the disagreements among botanists that had resulted from so doing. He would prefer calling fossils such as those described "cryptogamous forms from certain strata." He was doubtful also whether the supposed petrified starch was not merely orbicular silex. The chairman remarked on the four different conditions exhibited by existing tree ferns, first, with roots running down the stem: secondly, the lower portion with oval scars; these are, thirdly, farther up the stem, rhomboidal vertically; and, fourthly, higher up still, rhomboidal horizontally; so that were the plant fossil, distinct genera and species might be founded upon the different parts.

MANCHESTER

Literary and Philosophical Society, March 21.—Mr. E. W. Binney, president, in the chair. Dr. John Hopkinson was elected an ordinary member of the society. "On the Mechanical Equivalence of Heat," by the Rev. H. Highton. The following is an abstract of the arguments as given in the paper and brought out in the subsequent discussion:—1. The author apologised for having mentioned other names in connection with great discoveries which were undoubtedly due primarily to Dr. Joule, and spoke of the very great value of Dr.

Joule's experiments, even when he did not agree with the deductions drawn from them. 2. The subject is of extreme importance both for the interpretation of physical phenomena and or determining what limits are assigned by the stern laws of nature to the exercise of man's mechanical and scientific skill. 3. No doubt Dr. Joule has ascertained the heat ordinarily derived from the destruction of energy, by means of friction with various substances; but it has been assumed, *in defiance of facts*, that the numerical relations which connect heat and energy in the case of friction hold good when energy and heat produce or destroy each other by any other means. 4. In the case of friction itself, energy is not transformed simply into heat, but partly into heat and partly into another kind of energy, which is involved in the expansion of the solids or liquids acted on. 5. No doubt the coincidence between the mechanical equivalent of heat, found by Dr. Joule from friction, and that by M. Favre from working a magnetic engine, seems very striking; but (1) the value of Favre's experiment disappears on examination. It was but a single experiment, either never repeated, or never repeated with the same results; in a very delicate experiment there was only the difference of 300 units out of 18,000; and even the permanent enlargement which always takes place in magnets which are in use might account for this; and (2) numerous and long-continued experiments by M. Soret show results entirely discordant with the single one of M. Favre. 6. It seems incredible, that with the imperfectly constructed engine used by Joule and Scoresby, they should at the very first trial have succeeded in utilising two-thirds of the magnetism evolved, or capable of being evolved, by their battery; and Dr. Joule now tells us that according to his latest calculations of the mechanical equivalence of heat they utilised six-sevenths of the power of the battery. The only conclusion we can arrive at is, that the real power of the battery, and therefore of a grain of zinc, must have been much greater than he calculated. 7. For consider the disadvantages under which the engine acted: (1) the temporary and permanent magnets were never nearer than $\frac{1}{4}$ of an inch apart. Though Dr. Joule assures us this does not affect the *power* of the engine, it certainly produces a waste of zinc, as the near approach of the magnets creates counter-currents which check materially the consumption of zinc. (2) The copper wire was not tested for conductivity; a subject little thought of at that time, and it is found that a very small impurity in copper wire will very, very largely diminish the power of an electro-magnet. (3) The iron was not tested for specific capacity for magnetism, yet this is a most important point which is even now but little appreciated. It is found practically that, if two electro-magnets be made from the very same piece of iron, most carefully prepared, with the very same length of the same wire, without the slightest assignable cause, one will sometimes have three times the power of the other. Hence I conclude that the maximum energy capable of being evolved by a grain of zinc must be very much greater than that assigned to it by Dr. Joule. 7. Dr. Hopkinson's argument, in his paper lately read to this society, virtually amounted to this—that a well-constructed magnetic engine will get no more duty from a grain of zinc than an ill-constructed one; and consequently, I presume, that magnets might be weakened to any extent, and removed to ever so great a distance from one another, without necessarily affecting the efficiency of the engine. 8. Dr. Hopkinson has in his criticism strangely substituted $(a-b)$ for (b). In Joule and Scoresby's paper, the consumption of zinc is expressed not by $(a-b)$ but by (b); and consequently the duty of a grain of zinc not by $\frac{W}{a-b}$ but by $\frac{W}{b}$; and when the magnets are stronger and approach nearer to each other, even if W be not increased, (b) is diminished. 9. My argument was this, that since the accepted theory of the mechanical equivalence of heat is *that production of energy absorbs, and destruction of energy produces, a definite amount of heat*, if we find cases, as those of elastic wires, and water below its maximum density, in which destruction of energy produces cold, not heat, then the doctrine of the mechanical equivalence of heat cannot be true; we might with equal justice call it a mechanical equivalence of cold. It is no reply to say that such facts are simple deductions from the laws of thermodynamics. This would only show that the laws of thermodynamics are inconsistent with the doctrine of the mechanical equivalence of heat. 10. The argument from the fire syringe I withdraw, as inconclusive. But I think my case was sufficiently established without it. 11. Joule and Scoresby in their paper incorrectly assume that if the quantities of electricity in the current at different times be represented by (a) and (b), the heat varies as a^2 to b^2. This is only true where the resistance is the same. In the case before us the working of the engine introduces a fresh element in resistance. 12. Again by assuming that $(a-b)$ represents diminution of quantity of the current, *and* the diminution in the zinc consumed, *and* the heat converted into useful work, they involve the supposition either that less zinc produced equal heat, or that heat was changed into useful work which was never produced at all, and therefore could not be absorbed. In fact, there was no *proof* that any heat was absorbed at all. 13. It is said that in electro-plating, electro-magnetic engines, worked by steam, are found more economical than batteries. This is in cases where a battery of many cells would be required; which is always wasteful, as a large number of equivalents of zinc must be consumed to deposit one equivalent of silver or other metal. 14. Besides, there is a far greater advantage in changing work into electricity, than electricity into work. In the former case all, or nearly all, the work is effective; in the latter, a very small portion of the electricity has hitherto been utilised. —Dr. Hopkinson said that most of Mr. Highton's objections to the mechanical equivalent of heat appear to arise from a mistake as to what is meant by the term. The nature of this mistake may be best seen in the case of a perfect heat engine, of which t_1 and t_0 are the absolute temperatures of the source and refrigerator. Then from every unit of heat leaving the source we obtain $\frac{t_1-t_0}{t_1}$ J units of work. Now this a quantity variable with t_1 and t_0; it would be similar to most of Mr. Highton's arguments to infer that from a given quantity of heat a variable quantity of work could be obtained. But, of course, the case really is that of the unit of heat leaving the source, $\frac{t_0}{t_1}$ is lost in the refrigerator, whilst $\frac{t_1-t_0}{t_1}$ disappears *as heat* and is converted into the work done, and the principle of the equivalence of heat and work asserts that J is constant. It will be seen that this is the mistake Mr. Highton makes in his paper in the *Journal of Science* (end of article 6). He seems there to imagine it stated, that the work done is equivalent to the whole heat thrown into the gas, and he fails to perceive that a certain portion is used to raise the temperature of the air or turpentine. This will make my criticism of his paper in the *Chemical News* clearer. Mr. Highton argued against the mechanical equivalent, and what I pointed out was, that the chemical energy, which was converted into mechanical effect and not used to heat the wire, was proportional to $a-b$, that therefore, in order to prove that there was no mechanical equivalent Mr. Highton must show $\frac{W}{a-b}$ is variable. I do not assert that a badly constructed engine will get as much heat from fuel as a good one, but merely that the work done and the heat, which has disappeared as heat and been converted into work, are in a constant ratio. Now as regards Mr. Highton's argument from the case of elastic wires—that the wire will be cooled when stretched follows from the two laws of thermodynamics, a proof may be seen in Tait's Thermodynamics, p. 105. Mr. Highton replies, "Quite true; but this only shows that one of the laws of thermodynamics is inconsistent with the doctrine of the mechanical equivalence of heat." Now the first law of thermodynamics asserts nothing else than that there is a mechanical equivalent, constant in all cases; whilst the second law, as usually stated, involves the first law, and involves nothing else but Carnot's axiom and the principle that in conduction heat flows from the hot to the cold body, both of which no one will doubt. Mr. Highton's reply is very similar to stating that one of Kepler's laws is inconsistent with the planets moving in ellipses. What Mr. Highton proposes as a paradox is then a necessary consequence of the principle he attacks. Though the doctrine of the mechanical equivalent of heat finds its firmest basis in the immortal experiments of Dr. Joule, the fact, that assuming it we can explain many phenomena, is a valuable supplementary proof.

Edinburgh

Royal Physical Society, February 22.—Dr. Robert Brown, President, in the chair. "On the Glacial Epoch," by the Rev. P. A. Brodie. The author of this paper proposed three questions—(1) Is he correct in supposing that the popularly received opinion with respect to the glacial epoch regards it as a period of com paratively limited duration, intermediate between the Tertiary and Quaternary eras, when a freezing climate prevailed contemporaneously over a great part of the globe? (2) Has he stated with sufficient distinctness the facts adduced in support of that opinion? (3) Do the arguments which he has brought forward prove the opinion to be erroneous?—"Notes on the Sea Otter (*Enhydra marina*, Flem.)," by Pym Nevins Compton.—"On the Tailless Trout of Islay," by Colin Hay and Peter M'Kenzie. Mr. Peach, before reading the communication he had been entrusted with, wished to say that a gentleman whom he met at the house of a mutual friend, mentioned the Tailless Trout of Islay, and as this excited Mr. Peach's curiosity, the gentleman procured from Messrs. Hay and M'Kenzie the bounteous supply now laid before you. The communication was kindly made in reply to questions put to them by Mr. Peach:—"The locality of the loch is about 1,000 feet above the level of the sea, and is on the estate of Mr. Finley of Elenlossit, Islay, and at its highest water is not more than an acre in extent. It is so shallow that a man could wade all through it; the bottom loose stone quartz, same as the surrounding mountains, and we think it is the most elevated piece of water on the island in which trout exist. It is named Lochna Maorichean, meaning that a species of fresh water 'limpet' or 'whelk,' is found on its shores, but we can say nothing about these, all we have gone there for was to capture some of its strange denizens; as to its other productions, there are small tracts of weeds here and there lying on the surface of the water, with soft pulpy stems; of the parasites of the fish or in the water we cannot speak.—Dr. J. A. Smith exhibited a specimen of the *Cottus Grœnlandicus* (the Greenland Bull-head), recently taken at the Firth of Forth.—Mr. David Grieve exhibited a photograph of the Queensland Cicada, or as it is popularly termed, Locust.

MONTREAL

Natural History Society, Feb. 27.—The President, Principal Dawson, F.R.S., in the chair.—The President exhibited illustrations of new facts in Fossil Botany. The following is an abstract of his remarks:—"The first point mentioned was the occurrence in the Devonian Shales of Kettle Point, Lake Huron, of beds containing immense quantities of spore-cases, probably of *Lepidodendron*. These beds are referred by the Geological Survey to the horizon of the Genessee shales of New York, and are stated to be twelve or fourteen feet in thickness, and to extend over a considerable area of country. Specimens in the collection of the Survey show that the bituminous matter which causes the combustible quality of the shale, is due entirely to the immense quantities of spore-cases present, which, under the microscope, appear as flattened discs scarcely more than one hundredth of an inch in diameter. Specimens of the trunks of *Lepidodendron Veltheimainum* and *Calamites inornatus* occur in the same beds. This is probably the oldest bed of fossil spore-cases known; but in later geological periods similar beds occur, the Tasmanite, or 'white coal' of Tasmania, which consists of spore-cases of ferns, being a notable instance. The author next referred to the discovery of specimens indicating the existence of three or four species of Tree-Ferns in the Devonian of New York and Ohio. He had received from Prof. Newberry of New York a specimen, showing the upper part of a stem with five leaf stalks attached to it. This he had named *Caulopteris Lockwoodi.* Three other specimens collected by Prof. Newberry in Ohio indicated the existence of three distinct species belonging to two genera. The two most important had been named by Prof. Newberry *Caulopteris antiqua* and *Protopteris peregrina.* They are from the Coniferous Limestone, and thus carry down tree-ferns to the bottom of the middle Devonian. One of them has the cellular structure and vascular bundles in such preservation as to show their microscopic structure, which is precisely similar to that of modern ferns."—Mr. A. R. C. Selwyn, Director of the Geological Survey of Canada, read a paper "On the Occurrence of Diamonds in New South Wales," by Mr. Norman Taylor, late of the Geological Survey of Victoria, and Professor Thompson, of the University of Sydney.

PARIS

Academy of Sciences, March 27.—The hall was pretty well filled, and the correspondence was rather heavy. Letters from the provinces and from foreign parts were numerous, as the insurgents had not taken possession of the Post Office, and communications were not stopped between Paris and the outer world. M. Faye presided over the sitting, which was as orderly as in former times. No trace of public emotion was to be seen in the hall where the scientific assembly meet. Numerous details were given of the meteor which was seen on the 17th inst. in southern France, and left behind an immense luminous track. These details were very welcome, as during the investment certain bold theorists maintained that falling stars, bolides, and meteorites, were produced by the same causes. New facts having been brought forward at the last sitting to show that atmospheric changes are produced in high altitudes and gradually manifest themselves in the vicinity of the air, M. Wilfred de Fonvielle sent a communication upon the truth and genuineness of this observation. He quoted letters he had received from M. Buys Ballot, the learned director of the observatory at Utrecht, when he was waiting for a favourable wind in order to return to Paris by an aërial expedition during the investment. And he concluded by showing that the best way for ascertaining the state of things at a high level was to try scientific ascents. The Academy appeared to be much pleased with the idea, but it is impossible for it to recommend the application of the scheme as long as order is not established in Paris. M. Delaunay and M. Sainte-Claire Deville disputed as to the meaning of the thermometric measures which had been taken during the investment of Paris at the observatory at Montsouris and in the Jardin des Plantes. The distance of the two stations is something less than a mile, and the difference in altitude is about thirty feet. This circumstance may account for the difference in the two sets of observation.

DIARY

THURSDAY, APRIL 6.

LINNEAN SOCIETY, at 8.—On the stigmas of *Proteaceæ*: G. Bentham, Pres. L. S.—On the generic nomenclature of *Lepidoptera*: G. R. Crotch.
CHEMICAL SOCIETY, at 8.—On Burnt Iron and Burnt Steel: W. Mattieu Williams.—On the formation of Sulpho Acids: Henry E. Armstrong.

SATURDAY, APRIL 8.

ROYAL SCHOOL OF MINES, at 8.—Geology: Dr. Cobbold.

TUESDAY, APRIL 11.

NOTICE

We beg leave to state that we decline to return rejected communications; and to this rule we can make no exception.

THURSDAY, APRIL 13, 1871

THE PROPOSED SCHOOL OF PHYSICAL SCIENCE AT NEWCASTLE-UPON-TYNE

THE proposal to found a College in Newcastle for the teaching of Physical Science needs from us more than a mere passing mention. The idea of such an Institution is not a new one, indeed it is only justice to the coal-owners, chemical manufacturers, and engineers of that busy centre of commercial enterprise, to say that they have long confessed to a sort of shame that youths, intended for responsible positions connected with the various industries on the banks of the Tyne, Wear, and Tees, have had to seek their scientific training in metropolitan or continental schools; whilst young men a shade lower in the social scale, with no disposition to undervalue such knowledge, have had to depend upon their own limited resources for its partial acquirement, with the alternative of remaining in entire ignorance. The feeling of soreness on this point had attained sufficient force fifteen years ago to induce the North of England Institute of Mining Engineers to take preliminary steps towards establishing a college for the teaching of practical science. Meetings were held, architects consulted, plans drawn, and eventually those interested in the project were informed that about 35,000*l.* would be wanted from them if they were really in earnest. The Duke of Northumberland (Duke Algernon) was applied to, and his response was characteristic; it amounted practically to this:—"Raise 30,000*l.* and I will make it 40,000*l.*, but while you are about it, do the thing well." One would have thought that such an offer to so wealthy a body was equivalent to an order for the buildings to be advanced without delay. Unfortunately interests began to clash, individual promoters had pet ideas which they were unwilling to sacrifice, and there was no agreement as to the way the scheme should be carried out. The University of Durham, it was admitted on all sides, must have some share in the work, and no one could suggest a basis of connection that was mutually satisfactory, so by the end of the year 1855 the North of England had heard the last of the proposed "British College of Practical Mining and Manufacturing Science." It is perhaps no wonder if younger men, looking back at Duke Algernon's munificent offer, have accustomed themselves to think, "we would not have done as our fathers did."

One good result, however, had accrued from the failure. The necessity for scientific and technical education had been admitted, and public attention had been directed to the entire absence of local facilities for systematic teaching in those branches of theoretical knowledge most concerned in the industries of the North.

For a time the idea of an independent establishment in Newcastle seemed to be abandoned, and people were disposed to look to Durham University for a solution of the difficulty. The position of Durham was discussed, the revenue of its University talked of, and the relation of its expenditure to its educational results seriously debated—the outcome of all which was the appointment of a Commission to inquire into the administration of its various endowments. At this time the scientific instruction of the University amounted to twelve lectures annually from a Reader in Chemistry, some teaching from a Reader in Natural Philosophy, and a very few lectures from a Reader in Medicine. After the sittings of the Commission, the Senate took powers to establish a school of physical science in the faculty of Arts and to endow chairs therein, but as the stipends for these chairs were not forthcoming, their powers were never practically exercised. The readership in natural philosophy for some reason became vacant a few years afterwards, and as no fresh appointment was made, teaching in that department ceased even nominally to exist. We may be spared going into details as to the extent of the classes in the other two subjects; suffice it to say, that at the present time the physical science teaching supposed to be accomplished in Durham by the University cannot be regarded as anything more than the merest apology.

We have omitted any mention of Astronomy. Durham University has an Observatory and an Observer,—it has also a "Professor of Mathematics and Astronomy." We trust we do the present worthy occupant of the chair no injustice in supposing that his occupation has rested in the former rather than the latter branch of knowledge. With the Readership in Hebrew also on his hands, more than this could scarcely be expected.

Some knowledge of the history of previous movements, such as has been attempted in the above remarks, is needed if we would understand rightly the *status quo* at the commencement of the revived agitation.

It has been a matter of wonder to many that the northern coal owners and engineers, a body wealthy enough for almost any undertaking, and amongst whose faults cannot be reckoned want of regard to their own interests, even in that wide sense which embraces a care for the technical education of the rising generation, have remained passive during the long period which has elapsed since the failure of their first scheme; the more so as they appear to have in their "Institute" an organisation fitted to take the initiative in any public movement connected with theoretical or applied science. We are given to understand that one chief difficulty has been the want of house accommodation. The "Wood Memorial Hall," a building imposing in its design, if somewhat odd in its sculptural decorations, is expected to supply this deficiency, and its approaching completion indicates the opportunity for another effort. The new structure closely adjoins the buildings of the College of Medicine, the Natural History Society, and the Literary and Philosophical Society, suggesting lecture-room accommodation, a museum, and a library, ready to hand.

Meanwhile, a change seems to have been gradually taking place in the views held by those in authority at Durham; and when the Institute determined to invite all interested in the subject to a preliminary meeting a few weeks ago, it was with the conviction that a much more liberal response might be expected from the University than any hitherto accorded to proposals in which residence in Durham formed no part. As this first meeting appears to have been one for the expression of opinion only, and as this was elicited by the reading of a non-official letter from the Dean of Durham (*ex officio* Warden of the University) it is needless for us to dwell upon it further than to note the influential nature of the gathering, its unanimity as to the necessity for a thoroughly efficient school of physical science, and the determination that Newcastle was the only centre in which such an institution would have any chance of success.

At the adjourned meeting, the Dean of Durham and the Rev. Joseph Waite attended on behalf of the University, and as the proposals contained in the Dean's speech on that occasion seem to have been accepted as a general basis for the establishment of the College, we cannot do better than summarise them. They are roughly as follows :—

A College to be established in Newcastle for systematic teaching in Physical Science—literary subjects for the present to form no part of the curriculum.

Four Professorships to be constituted :—1. Pure and Applied Mathematics; 2. Chemistry; 3. Experimental Physics; 4. Mineralogy and Geology.

The curriculum of instruction to extend over two years; examinations to be held for degrees or diplomas in Physical Science, or other honorary distinctions subsequently determined upon.

Turning to the question of funds—the working expenses, including an adequate provision for the proposed chairs, were estimated at not less than 2,000*l.* per annum, in addition to the amount that might be received from students' fees.

Durham University offered to place in Newcastle two professors—one in Chemistry, the other in Experimental Physics—and to found ten scholarships, each of the value of 20*l.* per annum : five for first year, five for second year students. This offer was to be understood to extend to six years, but would be made in perpetuity if the results were such as to justify it. The government of the college to rest with a Newcastle board, upon which the University should have representatives. The Professors to be officers in the University, and degrees to be conferred in Durham; the examinations, on the other hand, to be conducted in Newcastle.

The one condition attached to the offer was that Newcastle should find a similar endowment of 1,000*l.* per annum, guaranteed for not less than six years.

The meeting appears to have been an eminently practical one, for more than half the required sum was subscribed in the room, and we learn that the amount named has since been considerably exceeded without any active canvass having been resorted to. The offer was naturally considered as accepted, and a Committee appointed to take steps for the carrying out of the scheme. The names of Sir W. G. Armstrong, the Rev. Dr. Lake, Mr. I. Lowthian Bell, Mr. Albany Hancock, and Mr. Newall, in connection with the executive, will carry assurance far beyond the northern counties that whatever is taken in hand will be efficiently accomplished.

The general design, sketched by the Dean of Durham, is so excellent that we are but little disposed to criticise its individual features, especially as the details which have been made public have not been put forward as representing foregone conclusions, so much as with the intention of supplying a basis for discussion.

If we read the scheme rightly, Durham is to provide two Professors and ten annual 20*l.* scholarships, and Newcastle to do likewise. Surely twenty scholarships in a newly-established college is an excessive allowance. Possibly this is not intended; at any rate such expenditure of funds would scarcely be entertained by the governing body without some reason not apparent to those less conversant with the requirements of the particular case.

Again, the selection of subjects as laid down by the Dean does not seem to be altogether happy. No scheme of scientific education in the present day can be regarded as satisfactory in which Biological Science is entirely ignored. It is true that the field of biology is too wide to be traversed in detail by a single lecturer or covered by a single course, and were the thing possible it would not be desirable. But it would be perfectly practicable for a Professor in Natural History to give in a short series of lectures much general information as to the organisation of the animal and vegetable kingdoms, and to select some special subject, either zoological or botanical, for more detailed exposition; and, as a means of training the observing powers, no portion of the curriculum would be so valuable. A college devoting its entire energies to one class of natural phenomena, to the exclusion of studies pertaining to natural objects and the phenomena of the organised world, can have no claim to be called a school of physical science in any wide or great sense.

Newcastle has already a position in respect to Natural History Science, and with an admirable Museum at hand, it would be a blot on the undertaking if its abundant local resources were not utilised.

THE UTILISATION OF NATURAL HISTORY MUSEUMS FOR SCIENTIFIC INSTRUCTION IN GERMANY

II.

THE German Museums of Natural History, founded for educational purposes, and connected with the various Universities, are by far the most important and influential. Those attached to the Universities of Berlin, Vienna, and Munich, are very large establishments, consisting of several sections which are independent of each other; and the aim pursued in each is to render the collections as complete as possible. Hence, although their chief purpose is to serve as schools of instruction for the students, they offer to the specialist abundant materials for original research, and have grown into attractive places of public resort. Those belonging to the smaller Universities are limited to instructive series of types; some, however, excel in one or more special branches. The teachers of the University are always the directors of the collections; thus the Professor of Zoology is the responsible head of the Zoological Museum, the Professor of Mineralogy of the Mineralogical, the Professor of Botany takes the charge of the Botanical Gardens, and so on. The appointments to the professorial chairs are not thrown open to competition; and the system of testimonials, humiliating alike to the candidate and his supporters, is unknown in German universities; men of repute for their knowledge and capability of teaching are chosen by the Senate, proposed to and appointed by the Government. We believe the Prussian Government has reserved to itself the right of appointment almost independent of the Senate, but, of course, is guided by the advice of men able to judge of the merits of the candidates proposed.

The lectures on the various branches of Natural History are either given in the Museum itself, or in a place adjacent. Each course occupies from 50 to 100 hours during a term of four months and a half. Some professors go with their students through a complete course of elementary instruction, whilst others leave this chiefly to private study, devoting the greater part of their time to inducting their pupils into the method of especial research. The attendance of students at the lectures is ensured by the circumstance that the Natural Sciences form part of the objects in which medical men, chemists, and teachers, are examined before they are allowed to enter upon the exercise of their calling. We are informed that, at a University with nearly 700 students (each remaining generally eight terms), some fifty would attend, within one term, the course of Natural Philosophy, or Botany; about twenty-five that of Zoology, or Comparative Anatomy; from fifteen to twenty that of Mineralogy, or Palæontology; and about thirty-five that of Geology. These were the numbers usually seen in the lecture-rooms, but there were, of course, other students who were prevented from attendance by various causes. The majority of those students who are desirous of receiving a perfect scientific education, and have the means for it, take advantage of the great variety of collections and instructors by prosecuting their studies at two or more Universities, finishing them at those places which offer the largest collections, and, in natural combination, the best instruction.

It may be mentioned here that the teaching of Science in German Universities is not entirely dependent on the public collections. Beside the staff of "ordinary" professors, there are younger men attached to the University, who have the right to teach, but can make only such use of the collections as the ordinary professor is disposed to grant. Most of them select, for their course of lectures, branches in the teaching of which they can dispense with the collections of the Museum—as, physiology of plants, histology and microscopy, history of development, general biology. This institution of "private docents," as they are called, is valuable not only to the students, but also to the body of instructors, inasmuch as it forms a preparatory school for men who intend to undertake the duties of an ordinary University teacher. The presence of an able and popular "private docent" has also not rarely had the beneficial effect of exciting to fresh exertions the ordinary professor, who had gradually lapsed into a course of stereotyped lectures. Nevertheless this institution can be regarded only as supplementary to the system of scientific education which is principally carried out in connection with the Museums.

We are not aware that there has ever been any lack of men combining an exact knowledge of some branch of Natural History with the aptitude for teaching it; nor have we ever heard of complaints that the duties of teaching seriously interfered with those of the curatorship; on the contrary, their union in one individual can have and has had only a beneficial effect. As teacher he knows best how to regulate the accessions and modify the arrangement of the collection, so as to meet the requirements of, and to be in accordance with, his system of teaching; and as curator he takes care that those parts which are not in direct connection with the lectures are not neglected, or that valuable specimens are not sacrificed for temporary purposes in the lecture-room or student's laboratory. Work in the Museum is as necessary for the training of the students as attendance in the lecture-room; and it is the duty of the teacher to devise suitable objects of research for his pupils. But if he had not the management of the collection, how could he be certain that the materials required are present, or will be made available? Would it be possible for him to superintend the student's work in a place where he is not the master? Were those duties assigned to two individuals, they would soon clash, to the injury of the service expected from the Institution.

The existence of numerous large or well-adapted collections, their utilisation for educational purposes, and the devotion of adequate time to instruction, are among the principal causes which have rendered the system of scientific education successful throughout Germany. But we must not forget that this success is due to the Universities only, and is limited to the classes receiving a University education. In the schools of lower degree, Science (with the exception of chemistry and natural philosophy) is only taught in the form of book-knowledge, in which the pupil takes but little interest, and therefore it has no great or lasting influence on the culture of his mind.

THE DESCENT OF MAN

The Descent of Man, and Selection in relation to Sex. By Charles Darwin, M.A., F.R.S., &c. In two volumes. Pp. 428, 475. (Murray, 1871.)

II.

THAT selection in relation to sex has been an important factor in the formation of the present breeds of animals was more than indicated in the "Origin of Species," and the theory has since been especially worked out by Professor Haeckel. It includes two distinct hypotheses. One is that in contests between males, the weakest would go to the wall, and thus either be killed outright, or at least debarred more or less completely from transmitting their characters to another generation. This may be regarded as a particular case of Natural Selection, and may be compared with the theory of protection by mimicry, suggested by Mr. Bates, and carried out by him and by Mr. Wallace. But though in the lists of Love the battle is often to the strong, even more frequently it is to the beautiful. This introduces a new process, of which the effects are not nearly so obvious as those of Natural Selection, either in its simplest form or in the more complicated cases of mimicry, and of sexual selection by battle. Many circumstances must combine in order that the most successful wooers shall have a larger and more vigorous progeny than the rest. In the first place, all hermaphrodite and all sessile animals may be excluded, and also those cases in which sexual differences depend on different habits of life. Mr. Darwin then shows that secondary sexual characters are eminently variable, and that males vary more than females from the standard of the species, a standard determined by the young, by allied forms, and sometimes by the character of the male himself when his peculiar functions are only periodical, or when they have been artificially prevented. Moreover it is the males who take the active part in pairing, and who not only fight for the possession of their mates, but display their colours, their voice, or whatever be their peculiar attractions, in order to gain the same end. This rule is confirmed by the exceptional case of the cassowary and a few other species in which the hens court the male birds, fight together in rivalry, and accordingly assume the brighter colours and more attractive shape usually worn by the male. Not only the parental and incubating instincts, but the usual moral qualities of the two sexes are in these cases reversed: "the females being savage, quarrelsome, and noisy, the males gentle and good." But it is further necessary to show that the females exert a choice among the males, and that the latter are polygamous, or arrive earlier at the place of pairing, as is the case with some birds, or else exceed in numbers, at least when both sexes are mature. On this point a series of observations is recorded relating chiefly to man, to domesticated mammals, and to insects. The rule as to transmission of male characters to both sexes appears to be that when variations appear late in life they are usually developed in the same sex only of the next generation, although they are, of course, transmitted in a latent condition through both; while, on the other hand, the differences which appear before maturity in the

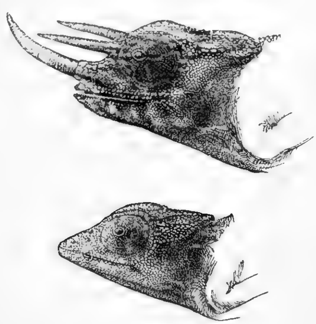

Fig. 2.—*Chamæleon Owenii.* Upper figure, male; lower figure, female.

parent are equally developed in both sexes when transmitted to the offspring. The numerous apparent exceptions to these laws of inheritance and of sexual selection are examined with wonderful fairness and fertility in resource. I may particularly refer to the discussion of the ways in which the young and adults of both sexes differ among birds. The extreme intricacy of some of the questions considered is best shown by a postscript in which, with characteristic candour, the author corrects "a serious and unfortunate error" in the eighth chapter.

The remainder of the first and the greater portion of second volume are occupied by a survey of sexual variations throughout the animal kingdom. Passing rapidly over the other invertebrate classes, the author devotes two chapters to the secondary sexual characters of insects. The weapons, the ornaments, and the sounds peculiar to the males of this vast group of animals are briefly described, and the remarkable analogy between insects and birds which is seen in so many other particulars is traced here also. The brilliant colours of many caterpillars, which, of course, cannot be due to sexual selection, offer one of the many difficulties which are faced, and this is explained by the aid of what the author terms Mr. Wallace's "innate genius for solving difficulties," as being due to natural selection. The bright colours warn the enemies of the caterpillars that they are unfit for food, and so benefit the latter, "on nearly the same principle that certain poisons are coloured by druggists for the good of man." Many cases are probably further complicated by mimicry, savoury caterpillars assuming the colours of distasteful ones so as to share in their immunity, in the same way that a druggist might label his bottles of sweetmeats "poison," to keep them from the shop-boy.

In the frigid classes of the lower Vertebrata one would think that sexual selection would have little play; yet Mr. Darwin gives several instances among fishes, amphibians, and reptiles in which weapons or ornaments, peculiar to the males, appear to have been acquired by this means. (See Fig. 2.) But it is in the great class of birds that the most complete series of examples is found, and our advanced knowledge of the habits of this class renders it

Fig. 3.—Head of *Semnopithecus rubicundus.* This figure (from Prof. Gervais) is given to show the odd arrangement and development of the hair on the head.

the best possible field for the exposition of the whole theory. Again and again our author forestalls the evidence adduced in the chapters on sexual selection among birds, when tracing its first obscure operation among lower classes, and falls back on the same stronghold when explaining its less obvious working in the mammalia.

Among birds the rivalry of beauty has led to far more striking results than has the rivalry of strength. Foremost of these is the power of song, which, in accordance with the law of the least waste, is usually confined to birds of inconspicuous colours, while the combination of the harsh note with the magnificent plumage of the peacock is a familiar converse example. The object of the adornment of birds is conclusively proved by its being, as a rule, confined to males, and often to them only during the breeding season, as well as by the pains they take to exhibit their beauties to the hens. The difficulty is to show the precise way in which the results have been attained by gradual selection. In two remarkable instances, the wings of the Argus pheasant and the train of the peacock, Mr. Darwin succeeds in tracing the gradations in the same bird or the same family by which these wonderful and elaborate ornaments have been brought to their present perfection. The woodcuts which illustrate these gradations are unfortunately too numerous to be reproduced here; they are admirably drawn, and convey the impression of the feathers as nearly as is possible by the means employed. Indeed, we may here remark that throughout these volumes the original cuts, generally of details of structure, contrast very favourably with the figures of species taken from Brehm's "Thierleben," which are feebly drawn and ill-engraved.

Sexual selection has, of course, been continually checked and modified by the never-ceasing influence of natural selection, sometimes, as in the case of the horns of stags, being only somewhat diverted, but often directly opposed, as when it produces dangerously conspicuous colours, and dangerously cumbersome ornaments. In the case of birds, Mr. Darwin holds that the usual tendency of sexual selection being to produce variation in males, its transmission to hen birds has been checked by natural selection. Mr. Wallace, on the other hand, believes that both tendencies have generally operated together, in opposite directions, so as to make successive generations of males more and more conspicuous than the primitive type, and those of females less so. The fact that, as a rule, young birds resemble hens in their plumage, is a strong argument for the former opinion, since most naturalists admit that early characters are the most trustworthy guide to natural alliances, *i.e.*, to true genealogy. To explain the transmission in some cases of brilliant colours (acquired probably by sexual selection, and therefore properly a male character) to both sexes indiscriminately, Mr. Wallace has framed the ingenious hypothesis, that the females have been protected from the dull uniformity threatened by natural selection, by their very general habit of building covered nests. Our author looks at the facts in a reversed way, and supposes that in most cases these hen birds, having inherited bright colours from the males, were led to the habit of building covered nests for the sake of protection.

Among mammals sexual selection has chiefly operated by increasing the size and strength of the males, and furnishing them with weapons of offence;* but besides allurements to the senses of smell and hearing, this class offers not a few instances, especially among the Quadrumana, of brilliant colouring being developed as a secondary sexual character. Here also we have the most striking instances of the production of defensive organs by the same process, as in the manes of lions, the cheekpads of some of the *Suidæ*, and possibly the upper tusks of that ancient enigma, the barbirusa. Lastly, it is in the class of mammals that we meet with cases of what may be called primary sexual ornament, as in *Cercopithecus cynosurus*, which make one wonder, with a thankful wonder, why such apparently obvious results are not more common. We must, however, admit that such adornment is not more disgusting, nor that of which we copy a figure more ludicrous, than the personal decorations of savages. Sir Joshua Reynolds says that if a European in full dress and pigtail were to meet a Red Indian in his warpaint, the one who showed surprise or a disposition to laugh would be the barbarian.* But who could stand this test when meeting *Semnopithecus rubicundus* or *Pithecia satanas?*

We must admit, notwithstanding such anomalies, that, on the whole, birds and other animals admire the same forms and colours which we admire, and this, perhaps, may be admitted as an additional argument in favour of their kinship with us. Some of the ugliest creatures (like the hippopotamus) appear to have been quite uninfluenced by sexual selection, while the magnificent plumes of pheasants and birds of paradise are undoubtedly due to its operation. That it has occasionally led to unpleasing results in birds and monkeys of aberrant taste, is no more strange than that all savages do not carve and colour as well as the New Zealanders, or that most Englishmen admire ugly buildings and vulgar pictures. The prevailing aspect of nature is beauty, and the prevailing taste of man is for beauty also. The *means* by which natural beauty has been attained are various. Natural selection is one, by which the healthiest, and therefore the most symmetrical forms survive the rest. Protective mimicry is another, by which fishes have assumed the bright colours of a coral garden and butterflies the delicate venation of leaves. Flowers again have in many cases obtained their gay petals and fantastic shapes from the advantage thus gained for fertilisation by insects. The successive steps which have led to the graceful forms and brilliant tints of shells, to the intricate symmetry of an echinus-spine or a nummulite, these are as yet untraced even in imagination.

But that many of the most striking ornaments of the higher animals, and almost all those which are peculiar to one sex, have been developed by means of sexual selection, is a conclusion which can no longer be distrusted. There remain doubtless many exceptions to be accounted for, many modifying influences to be discovered; but the existence of a new principle has been established which has helped to guide the organic world to its present condition. Side by side with the struggle for existence has gone on a rivalry for reproduction, and the survival of the fittest has been tempered by the success of the most attractive.

P. H. PYE SMITH

* The very general transmission of such weapons to both sexes may, perhaps, be explained by the need females have of means to defend their young.

* Discourse delivered at the Royal Academy, December 10, 1776.

HELMHOLTZ'S TONEMPFINDUNGEN

Die Lehre von den Tonempfindungen, von H. Helmholtz. (Braunschweig: F. Vieweg. London: Williams and Norgate. 3rd edition. 1870.)

THIS work traces the connection between physical and physiological acoustics, on the one hand, and the general principles and practice of music, on the other. Professor Helmholtz's qualifications for taking up this subject are unique. In each branch of science involved in the inquiry he has a reputation at least equal to that of any specialist in that branch. In the combination of eminently original mathematical power and consummate skill in physical and physiological research with the technical knowledge of a trained musician, he stands absolutely alone. It need therefore surprise no one that the volume before us, the first edition of which was published in 1862 as the fruit of eight years' work, has practically revolutionised the subject with which it deals. He begins by completely clearing up the nature of the *quality* (*timbre*) of musical sounds. He fixes his reader's attention on the *harmonics* which previous observers had recognised as accompanying a fundamental note. These, he shows, are no isolated phenomena, but invariable concomitants of nearly all musical sounds. In fact, what appears to be a simple note of any assigned instrument, is really a composite sound consisting of a number of different tones, all, however, members of a series connected together by a simple law. The *quality* of the sound depends on the relative intensities in which these *partial-tones* are present in the whole mass of sound (*Klang*) heard. Helmholtz illustrates his theory by determining the relative intensities of the audible partial-tones produced by the principal kinds of musical instruments, and also those corresponding to the different vowel-sounds of the human voice. He has also invented an apparatus by which the most important members of the complete series of partial-tones corresponding to a fundamental tone can be sounded with any assigned relative intensities, and which is capable of producing a tolerably close imitation of many sounds differing widely from each other in quality. These investigations occupy the first part of the work.

In the second part the nature of the difference between consonance and dissonance is explained, and thus a problem which has baffled natural philosophers since the time of Pythagoras finally solved. Here, again, the key to the solution is a perfectly well known phenomenon, the real significance and scope of which it was reserved for Helmholtz to recognise. Intermittent noises called *beats* had been observed whenever two notes nearly, but not quite, in unison with each other, were sounded together. Helmholtz asks what becomes of these beats when they are so rapid that the ear can no longer distinguish them as separate sounds. It had been supposed since the time of Young that they coalesced into a third musical sound, and thus formed the *combination ones* discovered as early as 1740 by a German organist named Sorge, but more generally known as *Tartini's tones*. Helmholtz proves that Young's view is erroneous. The beats never coalesce into a musical sound, but when they cease to be individually distinguishable, produce the sensation which we call discord.

This fact, taken in connection with the composite character of musical sounds, leads at once to Helmholtz's theory of consonance and dissonance. When two notes of different pitch are sounded, we have two series of partial-tones co-existing. If no member of the one series produces *beats* with any member of the other, the interval between the fundamental tones of the two sounds is an absolute consonance. If, on the other hand, beats *are* so produced, the consonance ceases to be absolute, and may be classed as a good or an imperfect consonance, or pass into a dissonance, according to the amount of discord involved in the combination. Helmholtz goes through the ordinary scale, and classifies the different intervals according to the above theory, his results tallying perfectly with those of the best writers on harmony. For the case of the comparatively unimportant class of sounds which have no upper-tones, Helmholtz employs a different method, which need not be detailed here. It is interesting to observe that his theory not only confirms some of the ordinary rules of musical composition, but is able to deduce principles which, though actually adopted by great masters, Mozart for instance, have never been explicitly stated by any theoretical writer. The third and last part of the work discusses the construction of musical scales, and the relation of each to its key-note. In this investigation æsthetical considerations necessarily assume an importance which they could not claim in the two earlier purely scientific parts of the work. As, moreover, musical technicalities of much complexity abound throughout the inquiry, it is not possible to give a popular *résumé* of the general results obtained in the third part.

The above is the most meagre outline of the subjects treated in the "Tonempfindungen." Indeed it is absolutely hopeless, within any reasonable limits, to try to convey an idea of the thoroughness, the laborious accuracy, the wonderful many-sidedness which appear on every page of it. The author, though a great mathematician, is fortunately too great an experimentalist to allow the laws of nature to figure as mere examples of the integration of differential equations, or as but affording subject-matter for new mathematical conundrums. Each acoustical law is thoroughly explained in popular language, with the most attractive richness and variety of illustration, a method of treatment infinitely refreshing to a student who has hitherto experienced only the husks of our arid examination-ridden manuals. All details of calculation are relegated to an appendix, and, though mathematics has its due honour given it, as a science absolutely indispensable for *thorough independent mastery* of any branch of physics, the most effective practical discouragement is given to the pedantic notion that no valuable knowledge can be gained without it. We may well doubt, indeed, whether the long exclusive domination of theory has made anything beyond mathematical symbols really *understood*. Cambridge honour-men will know what we mean by saying that an average wrangler, if asked what a *wave* was, would probably unhesitatingly answer—

$$“a \sin \frac{2\pi}{\lambda}(vt - x),”$$

and refuse to produce any further explanation. We desire for works like the "Tonempfindungen" a triumph in this country over English books "adapted for writing out in examinations" as decisive as the victory of the German armies on the soil of France.

SEDLEY TAYLOR

OUR BOOK SHELF

A Monograph of the Alcedinidæ, or Family of Kingfishers. By R. B. Sharpe, F.L.S., &c. Librarian to the Zoological Society of London. 4to. (Published by the Author. 1868—1871.)

THIS work reflects the highest credit upon its author, and will establish his reputation as an Ornithologist. Very few monographs published in England are so entirely satisfactory as this one, for not only have the several parts appeared regularly during the last three years, but the concluding double number just issued contains a copious and well-written introductory chapter on classification, geographical distribution, and literature, which renders the book a model of what such a work should be. The Kingfishers, although represented in our country by only one species, are especially abundant in the Eastern Tropics, where they exhibit a great variety of form and the most exquisite beauty of plumage. A considerable number of them are inhabitants of the forests, and never frequent water, subsisting on insects, small crustacea and mollusca, and the larger species even on snakes, lizards, and other reptiles, which they capture by darting down upon them from a branch just as our own species pounces upon a fish. Mr. Sharpe has been fortunate in securing the services of a young Dutch artist, Mr. Keulemans, who has himself studied birds in the tropics, and seizes upon their various attitudes with the happiest fidelity. He also surrounds his figures with little bits of appropriate scenery, so that a considerable number of the 120 plates with which the book is illustrated are beautiful pictures, as well as admirable representations of the several species. We do not hesitate to say that many of these plates are equal to the very best that have appeared in any illustrated work of Natural History. The body of the work consists of coloured figures of every known species of kingfisher, with full synonymy, careful description, and record of whatever is known of its habits. In the introduction, the classification of the species is carefully considered, only those generic groups being retained which can be characterised by marked structural differences. The whole family is first divided into two sub-families: the Alcedinidæ, or true kingfishers, characterised by a compressed keeled bill; and the Daceloninæ, or king-hunters, which have a depressed bill rounded or furrowed above. These are subdivided into nineteen genera, in which are grouped the 125 species of kingfisher now known. The groups are all characterised by modifications of the bill, feet, or tail, and a plate exhibits these generic characters at one view. There is also a tabular key of the species in every genus and of the genera in each sub-family, and the reasons are given for rejecting numerous genera proposed by other authors on insufficient characters. The geographical distribution of the species is then discussed in the same careful manner, an exact account of the known range of every species being given, as well as tables showing at a glance the distribution of all the species of a genus or group of allied genera; after which the results of the examination are ably summed up. Kingfishers present us with some of the most curious anomalies of distribution to be found in the whole class of birds. There is no part of the world so rich in peculiar forms of bird-life as America, more especially the southern half of it, yet it is the poorest of all parts of the world in kingfishers, only eight species being found in the whole continent,—a continent with more rivers and more fish than any other! The single island of Celebes actually contains as many different kinds of kingfisher as all North and South America, while New Guinea contains more than twice as many. It is perhaps even a more extraordinary fact that there is no peculiar type of kingfisher in America, all the eight species belonging to one genus, and that genus found also in Europe, Asia, and Africa. In Africa we have three peculiar genera of kingfisher, and twenty-four peculiar species. In continental India there are only five peculiar species, and not one genus. The western Malay Islands (Indo-Malayan sub-region) have one peculiar genus, and eleven peculiar species; the Philippines, seven peculiar species; but the Australian region has no less than ten peculiar genera and fifty-nine peculiar species, or nearly half those of the whole world. The peculiarities of the island of Celebes are well shown by the kingfishers, for not only has it eight peculiar species and three peculiar genera, but one of the latter has affinities with an African genus. In discussing the general relations of this isolated group of birds to the rest of the order, and the mutual affinities of the genera, the conclusion is arrived at that they are most nearly allied to (although still very remote from) the hornbills; and their relations are expressed by a branching diagram, as well by a map of the genus on the plan of Professor Flower. A copious account of the literature of the family is also given, no less than 135 separate works being enumerated, with references to every species of kingfisher described or noticed in them. An elaborate paper on the anatomy of these birds by Dr. Murie, with a full index, completes this exceedingly valuable work, which will be equally acceptable to the naturalist for its detailed and accurate information, and to all who love nature for its beautiful and artistic illustrations.

ALFRED R. WALLACE

The Wind in his Circuits, with the Explanation of the Origin and Cause of Circular Storms and Equinoctial Gales. By Lieut. R. H. Armit, R.N. (London: J. D. Potter, 1870.)

ACCORDING to Lieut. Armit "all the various phenomena which occur in Nature are accounted for by one theory forming one law, and the force which governs and regulates everything, even to imparting perpetual motion to the world, is Electricity" (p. 122). When the reader is informed of the author's opinion that the east wind is formed of compressed vapour or steam (p. 57), that lightning and thunder are caused by the Arctic current descending to fill any vacuum that may suddenly be found in the warm currents below it, the "grating" of the currents against each other causing friction and lightning, and the sudden shock of the impenetrable masses the thunder (p. 68); and that, by an attentive study of his theory, it will in future "be as easy to foretell and evade a storm and keep in a fair wind, as it is to drive over good roads and evade the bad ones, when you know the country you are driving through" (p. 126), he will understand that the book may be consulted out of curiosity, or for its psychological interest, but not for instruction in what concerns atmospherical phenomena and the laws which govern them.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Pangenesis

ON the introduction of Mr. Charles G. Leland, the author of the famous "Breitman Ballads," who was present at the reading of Mr. Galton's paper on Pangenesis before the Royal Society on the 30th ult., I have seen Mr. Lewis Ware, a young American gentleman who has been studying science in Paris since 1868.

By him I am informed that M. Leconte (I presume the physiological chemist of that name) is accustomed to mention in his lectures that he had frequently transfused the blood of one kind of animal into the veins of another; but it does not appear, in reference to those experiments, that any subsequent effects were noticed, as regards the offspring of such animals.

M. Leconte, however, further relates that once, not by way of experiment, but in order to save life, endangered, it must be supposed, from the occurrence of previous hemorrhage, he transfused into the veins of a white man blood drawn from a negro, and that the subsequent offspring of this white man by a white mother were *swarthy* in complexion.

Now, I cannot find any *published* record of M. Leconte's operation and its singular consequences, and it is impossible at the present moment to reach him by letter. I desire therefore to give publicity to what *seems* to be a conclusive proof of the theory of "pangenesis," with the view of eliciting a confirmation or refutation of the statement from some one who may chance to read this note, and who may have the necessary opportunities and leisure for further inquiry into the particulars of so very remarkable an incident. It is obvious that the number of children so affected, and the coincidence or absence of other changes in the hair, the form of skull, &c., require to be investigated, and the credibility of the parents fully authenticated.

10, Savile Row, W., April 8 JOHN MARSHALL

The Spectra of Aurora and Corona

So much attention has been drawn to the correspondence between the spectrum of the corona and that of the aurora, as to lead one to suppose that they were almost identical; or, at least, that the principal auroral line was also seen in the corona. But even this is not at all the case. As the readers of NATURE are aware, the light of the aurora is almost monochromatic, giving a spectrum of one bright line in the yellowish green (wave-length about 557), and three or four very faint bands, which are more refrangible. These last are only occasionally visible, and indeed, Angström, in 1869, had seen them but once, and that momentarily. It is with one of these faint bands that the 1,474 corona line (wave length 531·6) is said to coincide, and not with the bright line (wave length 557), which is entirely absent in the corona spectrum. Two more of the auroral bands are near to the F and G hydrogen lines, which are visible in the corona, but it is yet doubtful whether they coincide. It is not impossible that a faint H spectrum may be produced in the aurora by the moisture of the air, but I incline to attribute them to the low temperature air spectrum mentioned in my letter of February 7, and which has bands in nearly the same positions. From the extreme faintness of the auroral bands, it is of course impossible to measure their positions with great accuracy.

Under these circumstances it would seem rather premature to lay great weight on the supposed coincidence, and much careful work must be done both on gas spectra and on that of the aurora before we can say with any confidence that these lines are not due to gases already known to us under different circumstances of temperature and density.

I subjoin a table, giving the approximate wave lengths of the lines observed in the auroral and coronal spectra.

Lines of Corona and Prominences.		Lines of Aurora.		Observers.
Description	Wave length	Description	Wave length	
C Hydrogen	656	Bright line.	630 640*	H. R. Procter and others.
D Sodium	589

HENRY R. PROCTER

Royal College of Chemistry, March 28

* Seen on October 26 last year, but very rarely visible.

† Prof. Pickering considers this an error. My own measures give a wave length very slightly greater than those of Winlock and Angström.

The Aurora

THE splendid aurora which was visible here last night was probably seen in many other places, and from a comparison of data, perhaps the position of the luminous arch, which formed a conspicuous part of it as seen from here, may be made out.

At 10.30 it passed through the northern part of Corona, 12 Canum Venaticorum, and the head of Leo. At the time mentioned above, the whole of the light was a vivid green, but at about 10.40 red patches appeared, and at 10.45 rays shot up to a point situated about 4° S.S.W. of 12 Canum. The colour round this point was a most wonderfully dark blood red, and in many other parts of the heavens the same colour was seen, very different from the rosy light of last October.

About 11 clouds coming up covered the whole sky, and on their partially clearing away, the aurora was much decreased in brilliancy. The lurid red light reflected from the detached clouds which preceded the main body produced an exceedingly grand effect. The light was strong enough to read type of the size in which NATURE is printed.

On first observing the green parts with a spectroscope of one bisulphide prism, the only line distinctly visible was the green one; but by watching and opening the slit there came into view two bands at the more refrangible end, more sharply defined at the more refrangible side than at the other, and there also seemed to be a considerable continuous spectrum from the green line nearly to the least refrangible of the two bands.

In the red parts the red line was most brilliant, quite equal in intensity to the green one, and then even in the green light it was distinguishable with care and long watching.

York, April 10 T. H. WALLER

LAST evening, at about 9.50, my attention was called to a magnificent display of aurora borealis. A mass of light, composed of red and bluish-white streamers or rays, moved rapidly up from about W.S.W. to E.N.E., and the whole took the form of an arch overhanging for a short space of time the western horizon, while transverse waves of light, intensifying the lustre of the blue portions, and occasionally reaching almost to the zenith, rolled across the nebulous mass at intervals of about a second. Streamers projecting eastwards kept shooting out with great brilliancy, like sheet lightning, except that they were separated by a sharp line from the dark surrounding sky. Each flash made a fresh advance eastwards, like the skirmishers preceding an army, and a few bright crimson clouds alone kept nearly the same position throughout the display,—the finest of these was nearly in the S.W. At one time, when the flashes and waves had ceased, an umbrella-like radiation of red and white rays from the zenith attained great beauty. By five minutes past ten the sky had regained a more ordinary hue, but dull red clouds still remained, and in the west a white phosphorescence like early dawn. The night was calm and rather cold; the barometer 30·00 and steady. The wind had been gusty from E. in the afternoon. I had remarked during the daytime some very rare and beautiful modifications of cirrus and wave-cloud stretching from W.S.W. to E.N.E. (a direction coinciding with that of the aurora streamers), and crossed by bars at right angles to them at a lower elevation. The arrangement of these clouds showed that they were strongly acted on by electricity, as is generally, perhaps, the case with wave-cloud. May not vapours of this kind in a peculiar state produce the apparent polarisation of the sun's rays recorded by "J. W." in the *Times* of April 8? To-day, especially, between twelve and one o'clock, detached cumuli, driving rapidly from about E.S.E. and upper cirro-cumuli from E.N.E., have behaved in a manner quite unlike anything I have observed before. The only cirro-cumulus to be seen in the morning shot out branches in advancing and melted away between the branches, leaving a sort of skeleton of spine and ribs, which in their turn were dissipated. The cumulus motions were also unusual, for portions were suddenly arrested, remaining fixed, and then rose apparently and arranged themselves in bands more or less parallel until dissolved. The last phenomena only occurred, as far as I could see, below some whitish rays, extending across the sky from W.S.W. to E.N.E., parallel to the aurora streamers of last evening, and closely resembling the beams of light which often proceed from the sun when behind a cloud on a showery day. Either an aurora must be going on to-day, or the higher atmosphere is in a peculiar electrical state. The influence of these whitish bands on the clouds at a much lower level is at any rate remarkably powerful.

Wrexham, Denbighshire, April 10 F. R.

Solar Science at the pleasure of *Secret* Referees

IN the faithfully-recording columns of NATURE for March 30, at p. 434, is a much required abstract of Mr. Stone's important paper, recently communicated by him to the Royal Society, London, on the connection between terrestrial temperature and sun-spot phenomena. By comparing the curves of mean annual temperatures during the last thirty years (as observed, ready to his hand, by his indefatigable predecessor Sir Thomas Maclear) with another curve constructed on Wolf's observations of sun-spots, Mr. Stone has been enabled to deduce, almost immediately after arriving on his new scene of labour at the Cape of Good Hope, first, that there is an approximately decennial period of such temperature, and so similar to that of the sun-spots as to indicate more than a mere coincidence; and secondly, that the sun-spots are not to be looked on as the direct ages of thent temperature variation, but that either phenomenon results from some general change of solar energy.

As Mr. Stone expressly mentions "that he had not the slightest expectation, on first laying down the curves, of any sensible agreement resulting," I presume that he is not aware that upwards of a year ago I both sought the honour and experienced the grief of communicating to the self-same Royal Society of London an almost exactly similar research, resulting in almost the same solar conclusion; my foundation matter being the mean annual rock-temperatures observed in the Royal Observatory, Edinburgh, during thirty-three years (twenty-four of them under my own supervision) with the recorded sun-spot and other solar phenomena by Schwabe, Wolf, the Kew Observatory, and other authorities, during the same period.

And yet why was Mr. Stone *not* acquainted with this previous work of mine, communicated to the very same London Society, at a time too when he was still in London or very close to it?

The answer is probably, that it was the work of the *Secret* Committee of the Royal Society appointed by the Council to report on my paper. For the Committee's first proceeding was to keep the paper shut up with themselves for upwards of seven months; and their next, to condemn it before the Council on several counts, the two chief of which seemed to be—first, that I had inveighed without occasion, in a note on a certain page, *against* British units and standards of linear measure; and secondly, that I was not to be allowed to compare the Edinburgh mean annual temperatures with sun-spot observations.

Touching the first objection, I showed that there was no such note or sentiment throughout the whole paper; and with regard to the second, I felt scientifically constrained to declare, that I could not consent to be denied the right of comparing so long, accurate, and indeed hitherto unsurpassed, a series of earth-surface temperatures as those of the Edinburgh Observatory, with acknowledged solar phenomena; especially when confining myself to merely trying and exhibiting for annual means whether there was, or was not, any sensible correspondence in time and manner.

For this rebellious opposition to the despotic dictates of the *Secret* Committee, my paper was instantly extinguished by the Council of the Royal Society; and I was put to the further indignity of receiving an unpleasant letter from the secretary, on merely requesting to know the names of the gentlemen constituting the said Committee, whose identity in the flesh is therefore still a problem. But now, see how speedily the *Nemesis* of deeds of darkness has overtaken those who dabble in them; for the newly-appointed Astronomer Royal at the Cape of Good Hope, in charge of the British Observatory which stands next in importance to Greenwich, one of the Royal Society's own Fellows too, has, moved by some most mysterious impulse, made that very subject, just banned by the carefully concealed sages who speak from behind a curtain, the material of his first scientific communication from the Southern Hemisphere; and, with even a cruel degree of polite attention, he has sent that paper, filled with their own forbidden matter, to the Royal, rather than any other, Society in London, to read aloud before their members.

Yet this chief and leading society's secret Star-chamber, though exclaiming, perhaps, to the South African astronomer, "*Et tu, Brute*," has not repented, at least in any generous or human manner; for they have left me both to find out from NATURE the whole character of Mr. Stone's paper just accepted by and read before them, and to form my own unaided conclusions.

Wherefore I cannot but wonder more than ever, and even with exceeding admiration, at what *any* Scientific Societies in the present day have got to do with that accursed thing in all national history represented by Secret Committees, secret members, secret judgments, *veiled* prophets, who may, and—as would most clearly be shown if the whole correspondence in this case were to be published—who do, blunder utterly in understanding a plain sentence of simple English, who likewise enact a mistaken rule to tie down some astronomers in their own business, prove themselves totally void of Christian charity and gentlemanly feeling, and all the time require the incense of passive obedience to their partial edicts and strange behests.

Is not this then a matter just as important as any that can occur in the interests of true science and unalloyed, for the Royal Commission now sitting on Scientific Education and the Advancement of Science to take account of! For, if that Commission fitly and fully represents the general government in these times of this free and enlightened land in which we live, it would seem to be one of their holiest duties to the nation at large, to see that a base political method of a past and exploded era of our history, after being driven with ignominy out of every other branch of government, be not allowed to linger in sequestered nooks and dark corners of State-supported or State-aided societies for scientific pursuits.

C. PIAZZI SMYTH

Ocean Currents

MR. LAUGHTON thinks (see his letter in NATURE of April 6) that the ocean surface current, which flows into the Mediterranean by the Straits of Gibraltar, is due to the preponderance of west winds over the Atlantic. Were this so there ought to be a similar current flowing into the Baltic; but on the contrary, there is a surface-current flowing out of the Baltic.

I am convinced that Dr. Carpenter is right in accounting for the currents at the entrances of both the Mediterranean and the Baltic by the differences in the degrees of saltness of different seas.

JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim

Sun Spots

SOME very remarkable maculæ appeared on the sun on March 28, 9^h 50^m A.M., which are of interest from the fan-like portion of the most westerly of the large spots having been much enlarged whilst under observation. The enlargement took place from the centre outwards, and occupied several seconds in its development.

W. H. WALENN

The Echoes of the Royal Albert Hall

THE following observations may assist in reconciling some of the conflicting statements respecting the above subject, and explaining their curious discrepancies:—

The shape of the building is nearly elliptical; for the sake of description I will assume that it is a true ellipse. The middle of the platform, down which Her Majesty walked on the occasion of the opening ceremony, corresponded to the major axis of this ellipse, the seats in the arena were arranged in rows at right angles to the major axis, and thus the middle row of these seats was placed across the minor axis. I sat on one of the chairs of this middle row, that against the edge of the platform, and thus was in the nearest available place to the geometrical centre of the building, and therefore well situated for one set of acoustic observations. I listened very carefully, and made the following notes:—

An invisible military band was playing for some time before the arrival of the Queen. This music was freely heard without any perceptible echo, but the outlines of the sound (if I may use such an expression) were slightly shaded, there was just that want of crispness and definition of individual sound which would be advantageous to an ill-timed band, but somewhat damaging to the display of one that was playing staccato passages with perfect unity.

When the Prince of Wales read his address I heard every word repeated with perfect distinctness, the echo was pure and single, the two voices appeared like those of a prompter and a faithfully repeating speaker. The echo was remarkably well defined, and nearly as loud as the voice of the Prince.

When the Queen replied, her words were also repeated, but far less distinctly. This was a respectful whispering echo. When Santley sang a solo, there was no distinct echo, only a slight confusion of sound; but every note of Madame Sherrington's solo was most vexatiously mocked, but not so distinctly as the words of the Prince of Wales. A slight murmur accompanied the band, but it required a strain of attention to detect any definite echo.

The above is a description only of what I heard.

A friend who was sitting at the other end of one of the middle arena seats, *i.e.* near the boxes, or circumference of the ellipse, did not hear these echoes at all, and I have since learned that this was the case with others seated in boxes on either side of the hall.

The explanation of these facts is not difficult. On both sides of the organ, which occupied the south end or vertex of the ellipse, are unbroken curved wall spaces above the choir, covered with wooden panels or lining, a material well adapted for the reflection of sound. Beyond these bare spaces the boxes begin, and extend round the circumference till they reach the bare wall-space on the opposite side. There can be no regular reflection from the large area covered by the boxes when these are filled with people, but there must be such regular reflection very distinctly effected by the small bare portion of the curvature on each side of the organ.

If the curvature of this bare wooden wall-space were a true parabola, and a sound were emitted from the focus of the curve, it would be reflected in straight lines parallel to the axis, and only extending to a short distance on each side of it. With the actual curvature a close approximation to this should occur, the echo of the sound thus emitted would travel along the platform and extend a short distance beyond it, and thus be distinctly audible to the beefeaters arranged along the platform, and to those who like myself were sitting close to it.

When the Prince read his address, he stood very nearly in the south focus of the ellipse, a little the east side of it. In facing Her Majesty his voice was projected directly towards that portion of the panelled curve which should theoretically supply the parallel waves of sound to my side (the west) of the platform. Thus the distinctness with which I heard the echo of his voice is explained, and also the absence of echo in those parts of the hall farther distant from its major axis.

Her Majesty was near the focus, but not so near as the Prince of Wales. Santley was considerably to the west, and Madame Sherrington was on the east of the focus, but not so far removed as Santley. The quality and pitch of Madame Sherrington's voice would of course assist in rendering the echo more distinct. The band and chorus being distributed between the focus and vertex of the ellipse, fulfilled their theoretical requirements by having no regular echo, nothing beyond an indefinable rumble.

That the distinct echoes I heard came from the wooden lining was evident to the sense. I have often amused myself by experimenting upon mountain echoes, and when there is no redoubling have usually been able to detect the direction of their issue, and to find the rock surface producing them. The echoes of the voices of the Prince of Wales, Her Majesty, and Madame Sherrington, were remarkably free from any degree of redoubling, and evidently came from the direction of the south wall.

The remedy for this is obvious enough. This blank wall space must be covered with some kind of drapery, or broken up by ornament. Drapery will promote absorption of sound, an irregular ornamental surface will convert the regular reflection into scattering reflection.

I listened very carefully for any indications of echo from the roof, but could detect none, either the velarium was quite effective, or the echo, formerly attributed to the roof, came from the walls, or my position prevented me from hearing the roof echo. As I was not present at the first experimental concert before the velarium was put up, I will not venture any opinion on these points.

My apology for publishing these details is that the subject of the acoustics of this Hall is one of vast importance, both in reference to the Hall itself, and the intellectual progress of the inhabitants of all great cities. If large masses are to be taught orally, we must learn how to construct buildings in which the human voice may be audible to assembled thousands. The Royal Albert Hall presenting the grandest, and, I think, we may now say, the most successful experiment ever yet made in determining the possible limits of oral teaching, every contribution to a knowledge of its acoustic properties is of great value. I offer the above simply as such a contribution of observations made from one point—perhaps the most important point, and hope that it will be followed by other observations from other parts of the building. By combining these a correct knowledge of the whole subject may be obtained.

W. MATTIEU WILLIAMS

Gum Dammar

IN a valuable article in the current number of the "Quarterly Journal of Microscopical Science" the Radcliffe Travelling Fellow alludes to the general favour with which Prof. Stricker and other eminent German workers, regard Gum Dammar as a substitute for Canada Balsam as a medium for the preservation and preparation of histological specimens. Mr. Mosely further points out an unfortunate mistranslation in the Sydenham Society's English edition of Stricker's work, in which *Dammar firniss* is translated Canada Balsam, and regrets that good Dammar firniss (*Anglice* dammar varnish) cannot be obtained in England, though the gum itself is sufficiently common. It so happens that I have made use of various home-made preparations of Dammar in preference to balsam for some time past. I have found that it not only is a substitute for the latter "torment to beginners," but that it possesses many advantages over balsam, *e.g.* it is easier to use, sets more rapidly, and is above all clearer, more perfectly transparent, and more dense. Perhaps many of your microscopical readers will be glad to learn that a very good "dammar varnish" is made and sent out in a suitable form by Mr. Walter White, of Monmouth, to whom I am indebted for my knowledge of some valuable formulæ for its preparation.

Hull H. POCKLINGTON

THE IRON AND STEEL INSTITUTE

IN NATURE for March 30, we called attention to the annual meeting of the above society, which had just commenced in London. The new President, Mr. Henry Bessemer, delivered his opening address on the afternoon of Tuesday, when there was a large and influential attendance of the members from Scotland, South Wales, the North of England, South Staffordshire, Yorkshire, and other districts connected with the industries represented by this Institute. There were also several gentlemen present representing Continental and American works. Various matters of considerable practical importance were introduced to the notice of those present by Mr. Bessemer, and it is understood that the attentino of the Council will shortly be directed to carrying out, as far as possible, the suggestions contained in the address. Perhaps the most important subject mentioned was the proposal for a new series of tests to ascertain accurately the relative strengths of iron and steel. Many of the data upon which engineers and manufacturers have now to depend are comparatively old, and refer to classes of iron that are not made so extensively as they were at the time the experiments were instituted. New classes of iron have risen into importance during the last few years, and steel has become a very valuable article for engineering construction, so much so that it is desirable the materials now available for use should be thoroughly tested, in order that their properties may be fully understood by engineers and ironmasters. The proceedings at the meeting on Wednesday and Thursday were of a varied and interesting character. The committee appointed to investigate the subject of distribution of iron ores in Great Britain, presented their preliminary report, in which they stated that they had received from gentlemen connected with the trade special communications upon the matter. They gave a *résumé* of the production of iron ore in the various districts, and in many cases they intimated that the mineral statistics published by the Mining Record Office did not accurately represent the quantity of material raised. Taking a general view of the production of iron ore in the United Kingdom, they remarked that attention is now being mainly directed to the development of those districts that yield the cheaper classes of ore, such as Northamptonshire, Lincolnshire, and Cleveland, and to those localities where deposits of hæmatite are obtainable. The great demand for the latter ores is stimulating research in every direction where there is a probability of this mineral being found, but the circumstances under which it was deposited are at present so imperfectly understood that it is impossible to estimate with any precision where these researches are likely to prove successful. The Committee was re-appointed, and we understand that it is their intention to proceed with the preparation of a more thoroughly comprehensive report upon the subject of their investigations, and that this will be presented at an early meeting of the Institute.

The Committee appointed to report upon the question of mechanical puddling stated that they had given considerable attention to the subject of their investigation. They had paid visits to the principal forges where furnaces for mechanical puddling were in operation, and they gave a detailed list of such works. With respect to the Continent, they reported that Mr. Menelaus had kindly undertaken to obtain from France a set of the apparatus used at La Haynge, to put the same in operation at Dowlais, and to ask the Committee to see it at work in due course. Had it not been for the Continental war this machine would long ago have been at work, but it was detained in transit, and has not yet arrived in England. The Committee intimated that they were making arrangements for obtaining the services of a practical engineer, and of a gentleman acquainted with puddling, to visit the different works, and thoroughly to investigate the merits of the various machines in existence. The Committee proposed afterwards to verify the statistics given in by this gentleman.

The subjects which these Commissions are investigating are of great interest and importance to the trade, and it is to be hoped that the gentlemen entrusted with the inquiries will be able to prosecute them to a satisfactory issue. The paper by Mr. F. Kohn on the production of alloys of iron and manganese gave rise to a discussion, in which it was asserted that the manufacture of spiegeleisen had at length become an established fact in connection with the iron trade of this country, the Ebbw Vale Company having recently succeeded in extracting that material from the spathic iron ores of the Brendon Hills. Considering that this company have devoted a long time to the solution of this important question, it is satisfactory to find that they have been fortunate in this matter. The results obtained by the Terre Noire Company in the production of a soft steel are very remarkable, as Sir W. Fairbairn testifies that in ductility this steel stands in the ratio of ·219 per unit of length to ·092 of the Bessemer steel manufactured at Barrow from hæmatite ore. The steel in question was made by the use of ferromanganese made by Mr. Henderson's process, and containing an average of 23 to 25 per cent. of metallic manganese. The pig iron is run directly from the blast furnace to the converters without mixing with other kinds of iron, and the rich ferromanganese is used instead of the ordinary spiegeleisen.

Mr. Walker read a communication on modern appliances for reversing rolling mills, which introduced a notice of the principal arrangements now adopted for securing reversing action in rolling iron and steel. This is a matter of great importance, and has engaged the attention of engineers for some time past. The principal systems are—First, by reversing motion of the ordinary locomotive type; and, secondly, by friction clutches. The latter plan was most particularly described. It was stated that the polls can be reversed at any speed, and the mills fitted up on this method are remarkably effective. Mr. Ferrie contributed a paper upon an improved form of blast furnace recently introduced into Scotland. This differs from the furnace in ordinary use by the addition of about 20ft. at the top, which is divided into four compartments, and the raw coal charged in at the top is coked in its passage down the vertical chambers. The practical results of the working of this furnace over a considerable period has been a saving of at least one ton of coal for each ton of iron produced. In the discussion it was maintained that the advantage derived by Mr. Ferrie from the alteration of his furnace were mainly due to increased height; but it was also advanced that with raw coal for fuel it would not be practicable as a rule to make furnaces 80ft. high work satisfactorily. Mr. Ferrie appears to have demonstrated that high furnaces using raw coal can be made to give as good results as are obtained in the more modern districts. Mr. Tate read a paper giving a very clear account of the distribution, extent, and value of the iron ores of Antrim, which are now coming into notice, and will doubtless very soon be extensively employed in the west coast and elsewhere in the manufacture of hæmatite iron. Mr. D. Forbes also read a paper on iron ore, his subject being a brief description of the central mining district of Sweden. He called attention to the immense deposits of iron ores of great purity that will soon be opened up by the construction of a railway which will give direct access to the North Sea, and will thus render it feasible to import the Swedish ores into this country. The discussion on the Sherman process was interesting, but showed pretty clearly that the practical men who had taken the matter up, and had investigated it thoroughly, had not been able to arrive at any satisfactory results from it. Considering the nature of the chemical substances applied in the treatment of the iron by this process, it was only natural that such negative results should be obtained.

We must not omit to mention the lecture by Prof. Roscoe on Wednesday evening on spectrum analysis in its relation to the manufacture of iron and steel. There was not very much to state with respect to recent discoveries in the application of spectrum analysis to the production of steel, but it was important that the trade should know exactly what they might, and what they might not, expect from this delicate method of chemical investigation. Prof. Roscoe, in a very able and lucid manner, laid before the members of the Institute all that is at present known about the subject. One discovery by Mr. Snelus is likely to lead to good results. He has found that by the aid of the spectroscope he can predict the exact length of time that a "blow" will last in the Bessemer converter, and he hopes to be able eventually to stop the operation at a time when a definite amount of carbon may be left in the molten iron, and thus the quantity of spiegeleisen required to produce steel of a given quality will be reduced.

The proceedings, on the whole, were of a thoroughly satisfactory character, and, considering the short time the Institute has been in existence, it seems highly probable that it will eventually occupy a position of much influence and importance.

NOTES

HIS EXCELLENCY the Lord Lieutenant of Ireland has been pleased to appoint Dr. R. O. Cunningham to the Professorship of Natural History in the Queen's College, Belfast. The newly-appointed Professor is well-known as an enthusiastic naturalist. The pleasant post of Professor to the most successful of the Queen's Colleges in Ireland is one that we are glad to see filled by the appointment of so estimable a man.

WE rejoice to be able to announce that the following Scholarships have been established by Gonville and Caius College, Cambridge, and hope it will not be long before all the other Colleges follow so good an example:—A Scholarship in Natural Science, tenable for four years from Lady-day, 1871, and of value from 60*l*. to 20*l*., according to the candidate's proficiency, will be awarded at this College in June next. The successful candidate will require to enter his name at this College forthwith, and to begin residence in October. There will be three distinct examinations, in any one (but in one only) of which the student may compete—namely, in (1) Chemistry and Experimental Physics; (2) Zoology, with Comparative Anatomy and Physiology; (3) Botany, with Vegetable Anatomy and Physiology. The examinations will be held on the 2nd of June. Candidates must send in their names, stating which subject they elect to be examined in, to Dr. Drosier, Gonville and Caius College, Cambridge, on or before the 15th of May, enclosing a certificate of good conduct from a graduate of one of the British Universities.

THE vacancy in the curatorship of the Leeds Philosophical and Literary Society has been filled by the appointment of Mr. Louis C. Miall, curator to the Bradford Philosophical Society. Mr. Miall is already favourably known in Leeds, through the very interesting and successful lectures on Geology which he delivered at the Philosophical Hall last year, and he is at present engaged in the delivery of a course of lectures on Botany at the same place. He is the author of various papers and publications on Botany and Geology, more especially as affecting the West Riding. Mr. Miall's candidature was strongly supported by Profs. Owen, Huxley, and Rolleston; and the Leeds Philosophical Society may be congratulated on his appointment.

WE are unable this week to give any report of scientific proceedings in Paris: during the civil conflict every scientific movement is paralysed. The sittings of the Academy are suspended; but should the siege be prolonged, they may probably be resumed at Versailles, although some of its members are detained in Paris by the Commune as hostages.

WE are sorry to learn that the Government of Nova Scotia, in resorting to the retrenchment system, has withdrawn the small annual grant heretofore made to the Institute of Natural Science, the only scientific society that colony possesses; and, moreover, one which for the past eight years has struggled to maintain a position creditable to itself and the country in which it is established. Surely the trouble and expense of publishing, setting aside the gratuitous mental labour of those members who have furnished the interesting papers which together form the eight annual parts, comprising two volumes of over 1,000 pages, should have been considered by the authorities of the colony before they acted in such an illiberal spirit. We trust, nevertheless, to see the Institute still progress in its career of usefulness.

WE have great pleasure in announcing that Mr. Julian Goldsmid, M.P. for Rochester, who is a Master of Arts in the University of London, has just made his University a handsome present of 1,000*l.*, to be paid in annual instalments distributed over ten years, towards the formation of a good classical library in the new building. The Senate have accepted the offer, with a hearty acknowledgment of its generosity; and a committee has already been appointed to begin the agreeable task of forming a classical library. We trust Mr. Goldsmid's generosity may be infectious. The *Spectator* suggests whether it is possible to secure for the University the late Prof. De Morgan's unique Mathematical Library, which probably contains the most curious collection of books on the history of mathematics to be found in England. The value of this collection is besides greatly enhanced by Mr. De Morgan's own numerous and characteristic annotations. Whether the library is to be disposed of or not, we do not at present know; but if it could be obtained, there would be a special fitness in securing it for the University of London, which would then have a really good start towards the formation of a fine classical and scientific library.

MR. ELWES, of University College, London, and Mr. Jude, of King's College, London, have been elected to Natural Science Scholarships at Christ's College, Cambridge, of the respective values of 70*l.* and 50*l.* per annum.

WE have to record another instance of American munificence towards Science. Vassar College has received a donation of 50,000 dollars to found a natural history professorship.

WE have received the first number of the 4th volume of "Sirius," edited by Dr. R. Falb, which promises to keep its old reputation as an excellent astronomical journal. It is accompanied by an admirable map of the stars of the northern hemisphere down to the 4th magnitude, the variable and double stars being indicated at a glance.

SEVENTY years ago some domestic rabbits were introduced upon Sable Island, a small sandy islet lying about a hundred miles off the Nova Scotia coast, and being left alone and not crossed in breeding, they have entered their feral state in liveries of beautiful silver grey, with white collars, intimating some remote affinities with bygone races.

AT the Natural History Society of Ireland, held on Wednesday, April 5th, R. P. Williams in the chair, Dr. A. W. Foot read a paper on "Irish Diptera." The list contained those species taken by him during the previous summer, and embraced sixty-five species belonging to thirty-nine genera. Mr. W. Andrews read a paper on the species of the genus Hymenophyllum met with in New Zealand. Some pretty sketches of scenery in New Zealand were exhibited by the author, who also laid on a table a number of illustrative dried specimens, which had been communicated to him by friends in America.

ON December 1 there was an earthquake at Tinnevelly in the Madras Presidency; and on the following day a slight earthquake was felt at Darjeeling, an English town in the Himalayas.

ON the 9th February there was a very strong shock of earthquake at Illapel in Chile. On the 11th February a strong shock of earthquake was felt at Valparaiso in Chile about 4 A.M. It is worthy of note that both these earthquakes occurred simultaneously with freshets from the mountains.

ON Twelfth Day an Indian woman of Cuzco in Peru, forty-five years of age, gave birth to a triplet of boys, one of whom survived. As this happened strangely enough on the day of the Three Kings, it excited the superstitions of the natives. The surviving boy was named Gaspar, after one of the kings.

COAL of excellent quality is said to have been discovered near the rich silver mines of Caracoles in Bolivia, about twelve miles from Calama.

IN a recent number of the *Scientific American* are short descriptions and drawings of two useful inventions:—a Washing Shield, consisting of a corrugated shield or armour which protects the arm and at the same time forms an effective surface for rubbing the clothes; and an Anti-snoring device, consisting of a leather band placed over the head and chin, which effectually closes the mouth during sleep.

FROM the Thirteenth Annual Report of the East Kent Natural History Society we learn that that body is "in much the same condition as at the end of the preceding year." The library has been largely augmented; there has been but one excursion; several lectures have been given; and fortnightly evening meetings have been established. The Committee appointed to report upon the flora of the district seems to have made but little progress. The Rev. J. Mitchinson, D.C.L., is the President; and Mr. George Gulliver, F.R.S., Secretary.

THE Malvern Naturalists' Field Club has issued in a neat volume its Transactions for 1853-70. It contains a large number of papers mainly illustrative of the natural history of the district, including catalogues of local birds, mollusca, lepidoptera, and fungi, with sketches of the geology of the Malvern Hills, and observations on the meteorology of Malvern. There is also an interesting sketch of the proceedings of the Society from its commencement in 1853, to the close of 1868, by the Rev. W. J. Symonds, F.G.S., President; and a long paper on "The Forest and Chace of Malvern: its Ancient and Present State; with Notices of the most remarkable old Trees remaining within its Confines," by Mr. Edwin Lees. This is illustrated by several well-executed engravings of some of the trees referred to; but we can commend neither the illustrations nor the matter of the same author's paper "On the Forms and Persistency of Arboreal Fungi." The volume, however, on the whole, is likely to be useful to the members of the club, and is a creditable production.

THE more general use of buffaloes for the purpose of moving timber in some of the forests of India has been recommended by the conservators of those forests which are situate on comparatively level or uneven ground as being more practicable and economical than elephants. It is found that there is great difficulty in some parts in obtaining sufficient fodder for the elephants, one of the consequences of which is that their health suffers, and this, when taken with the high price paid for them, causes considerable loss. Owing to the size and weight of many of the logs, however, which often lie in difficult positions, a few elephants are necessary; but in those forests where low trucks and carts can be used, it is said that a few pairs of buffaloes will do more work, and can be kept with less risk than elephants.

THERE is a plant in New Granada which, if our ink-makers could only grow in sufficient quantity in this country, would be a fortune to them. The plant in question (*Coriaria thymifolia*) is commonly known as the ink plant, and it is simply the juice that is used without any preparation. Its properties seem, according to a tradition in the country, to have been discovered during the Spanish administration. A number of written documents destined for the mother country were embarked in a vessel, and transmitted round the Cape, the voyage was unusually tempestuous, and the documents got wetted with salt water, those written with common ink became nearly illegible, whereas those written with "chanchi" (the name of the juice) remained unaltered. A decree was therefore issued that all government communications should in future be written with the vegetable juice. The ink is of a reddish colour when freshly written, becoming perfectly black after a few hours, and it has the recommendation of not corroding a steel pen so readily as ordinary ink.

A NEW *Wellingtonia gigantea*, or "big tree," forty feet and four inches in diameter, has been discovered lately near Visalia, in Southern California. This is thicker by seven feet than any other that has yet been found. A section of one of the "big trees" is now exhibited in Cincinnati, which is seventy-six feet in circumference and fourteen feet high; and, standing on the floor of the hall, it gives one a perfectly clear idea of the enormous size of the tree from which it was taken. The section was cut last year in the Mariposa grove, about two hundred and fifty miles south-east of San Francisco, and far up the western slope of the Sierra Nevada mountains. It was divided and hauled a hundred and forty miles to Stockton, on three waggons by seventeen yoke of cattle.

UNDER the title of "British Pharmacology" Mr. W. W. Stoddart is publishing in the *Pharmaceutical Journal* some interesting papers upon some of the British plants which are employed in medicine. Speaking of the presence of allyl in the horseradish, he says, "It is a very singular fact that the cruciferous plants produce compounds of sulphur and allyl that are so well known in the genus Allium, plants so dissimilar in habit and construction as to be in both exogenous and endogenous divisions of the vegetable kingdom. In every part of the world the garlic flavour seems to be a favourite. The Israelites of old regretted the loss of their leeks and onions. The Englishman likes the addition of a shallot, mustard, or horse-radish to his beefsteak. The Spaniard selects the onion, and the Asiatic assafœtida. Even the Brazilian has chosen the petiveria and sequieria, both of which have an alliaceous flavour. The whole of these owe their smell and taste to allyl, which in the onion tribe exists as a sulphide."

A DEPOSIT of alum of considerable magnitude has been found in the Kulhu Valley, in Madras. It was first found by shepherds. As a rule, the headmen of villages prefer even now not to disclose mineral discoveries.

MR. BLANFORD, of the Indian Geological Department, has been specially appointed to proceed to Damagoodiam in the Central Provinces to examine and report on the coal discovered by Colonel Henry.

FAVOURABLE reports of the Cinchona cultivation in the West Indies continue to be received. We learn that in the Jamaica plantations the trees are seeding plentifully, and that about 100,000 seeds of *C. calisaya* are now ripening. There are also 40,000 seedling plants of *C. succirubra* raised from Jamaica seed. One hundred acres of land over and above the hundred acres already established, have lately been prepared for planting in the coming spring, and there appears every prospect of a few hundred more acres being soon prepared to be put under similar cultivation.

FROM Asia Minor we get no scientific records of weather, but in their absence some information of a meteorological character is useful. The winter in Smyrna has been very mild, accompanied with heavy rains, but apricots had shown fruit. On the 29th the rainy season culminated in a flood of the river Metes, inundating the city of Smyrna in a way not known for more than half a century, while the great river Hermus also overflowed. Soon after the weather changed to a sharp frost, which will cause destruction among orange and fruit trees. It will be observed the weather is the reverse of ours.

THE Government of Madras has appointed four scientific gentlemen to annalyse the water of that Presidency.

DR. HERMAN CREDNER, of Leipzig, in a forthcoming number of Petermann's *Mittheilungen*, presents a valuable report upon the geology and mineralogy of the Alleghany system of the United States, accompanied by a detailed map of the region.

NEWSPAPERS do indeed bring intelligence to men of Science, but they bring error to the vulgar. We had made a note from an Indian paper of a hen which had hatched a chicken perfectly resembling a young kid, and created consternation in a whole kingdom concerned to know what misfortunes are portended. We are the more inclined to notice this valuable contribution to natural science, because now we find in a Smyrna paper, *La Réforme*, intelligence that the island of Crete is now busied with the fact, "well authenticated," that a woman in the village of Melikos has been brought to bed of two monsters having the form of serpents. Although they only lived two hours, so that the medical men of the island could not, if they had the requisite capacity, make any observations, the "fact" may cost the unlucky Turkish Government another insurrection. Cock-and-bull stories may sometimes be dismissed with contempt, but want of instruction in natural science may in this country and some others be of more serious moment; for ignorance is seldom bliss, but one of the great promoters of evil. Knowledge of natural science may prevent national discouragement in some cases, and in others stifle the spread of conspiracy and rebellion. The Aurora Borealis has in the east been connected with the Menzikoff note and been commented on by it.

A HANDSOME consignment of silkworms' eggs has arrived at Sydney with the appliances of a "magnanarie" from Japan, which may prove the foundation of a branch of Industry in New South Wales that shall vie with the production of wool and excel that of sugar. The Acclimatisation and Agricultural Societies have been directing their attention to the subject, and some of the best varieties of silkworm have been acclimatised by Mr. Charles Brady. In June last the Acclimatisation Society wrote to Sir Henry Parkes at Yokohama for specimens of the finest varieties of worms, with specimens of silk, cocoons, &c., and a complete set of sericultural implements. With kind alacrity he set to work at once to oblige the society, and so far interested the ex-Minister of the Interior, Prince Daté, on the subject as to receive from him gratuitously nearly all that was wanted.

A LONG and interesting letter by Mr. T. J. Monk, on the Breeding and Preservation of the Woodcock in East Sussex, appears in the *Field* of Feb. 25. The writer gives an account of the occurrence of this bird in seven districts of East Sussex, comprising twenty-one parishes, in all of which woodcocks have nested, and are nesting in greater or less numbers every year. On an average, Mr. Monk considers that from a hundred and fifty to two hundred nests might be found in these districts in most years; and states his opinion that, if never shot at after Feb. 1, and if the coverts were kept as quiet and undisturbed as possible during the breeding season, we might hope for a still further increase in the number of young birds.

EXAMPLES OF THE PERFORMANCE OF THE ELECTRO-MAGNETIC ENGINE*

SOME experiments and conclusions I arrived at a quarter of a century ago having been recently criticised, I have thought it might be useful to place the subject of work in connexion with electro-magnetism in a different and I hope clearer form than that in which I have hitherto placed it. The numbers given below are derived from recent experiments.

Suppose an electro-magnetic engine to be furnished with fixed permanent steel magnets, and a bar of iron made to revolve between the poles of the steel magnets by reversing the current in its coil of wire. Such an arrangement is perhaps the most efficient, as it is the most simple form of the apparatus. In considering it, we will first suppose the battery to consist of 5 large Daniell's cells in series, so large that their resistance may be neglected. We will also suppose that the coil of wire on the revolving bar is made of a copper wire 389 feet long, and $\frac{1}{16}$ of an inch diameter, or offering a resistance to one BA unit. Then, on connecting the terminals of this wire with the battery, and keeping the engine still, the current through the wire will be such as, with a horizontal force of earth's magnetism 3·678, would be able to deflect the small needle of a galvanometer furnished with a single circle of one foot diameter, to the angle of 54°23′. Also this current going through the above wire for one hour will evolve heat that could raise 110·66 lbs. of water 1°, a quantity equal to 85430 ft. lbs. of work. In the meantime the zinc consumed in the battery will be 535·25 grains. Hence the work due to each grain of zinc is 159·6 ft. lbs., and heat ·20674 of a unit.

I. In the condition of the engine being kept still we have therefore, current being 1·396, as shown by a deflection of 54° 23′,

1. Heat evolved per hour by the wire 110·66 units.
2. Consumpuion of zinc per hour 535·25 grains.
3. Heat due to 535·25 grains, 110·66 units.
4. Therefore the work per hour will be (110·66 -- 110·66) 772=0.
5. And the work per grain of zinc will be $\frac{0}{535{\cdot}25}=0$.

II. If the engine be now started and kept by a proper load to a velocity which reduces the current to $\frac{2}{3}$, or ·9307, indicated by deflection 42° 57′, we shall have

1. Heat evolved per hour by the wire $110{\cdot}66 \times \left\{\frac{2}{3}\right\} =$ 49·18 units.
2. Consumption of zinc per hour $535{\cdot}25 \times \frac{2}{3} = 356{\cdot}83$ grains.
3. Heat due to 356·83 grains, $110{\cdot}66 \times \frac{2}{3} = 73{\cdot}77$ units.
4. Therefore the work per hour will be (73·77 − 49·18) 772 = 18983 ft. lbs.
5. And the work per grain of zinc will be $\frac{18983}{356{\cdot}83} = 53{\cdot}2$ or $\frac{1}{3}$ of the maximum.

III. If the load be lesssened until the current is reduced to $\frac{1}{2}$ of the original amount, or to ·698, we shall have

1. Heat evolved per hour by the wire $110{\cdot}66 \times \left(\frac{1}{2}\right)^2 =$ 27·665 units.
2. Consumption of zinc per hour $535{\cdot}25 \times \frac{1}{2} = 267{\cdot}62$ grains.
3. Heat due to 267·62 grains $110{\cdot}66 \times \frac{1}{2} = 55{\cdot}33$.
4. Therefore the work per hour will be (55·33 − 27·665) 772 = 21357.
5. And the work per grain of zinc will be $\frac{21357}{267{\cdot}62} = 79{\cdot}8$ or $\frac{1}{2}$ of the maximum duty.

IV. If the load be still further reduced and velocity increased so as to bring down the cnrrent to $\frac{1}{3}$ of what it was when the engine was still, or to ·4653, shown by a deflection of the galvanometer of 24° 57, we shall have

1. Heat evolved per hour by the wire $110{\cdot}66 \times \left(\frac{1}{3}\right)^2 =$ 12·294 units.
2. Consumption of zinc per hour $535{\cdot}25 \times \frac{1}{3} = 178{\cdot}42$ grains.
3. Heat due to 178·42 grains $110{\cdot}66 \times \frac{1}{3} = 36{\cdot}89$ units.
4. Therefore the work per hour will be (36·89 − 12·294) 772 = 18988 ft. lbs.
5. And the work per grain of zinc will be $\frac{18988}{178{\cdot}42} = 106{\cdot}4$ or $\frac{2}{3}$ of the maximum duty.

V. Remove the load still further until the velocity increases so much that the current is brought down to $\frac{1}{100}$ of its quantity when the engine is still. Then we shall have

1. Heat evolved per hour by the wire $110{\cdot}66 \times \left(\frac{1}{100}\right)^2$ = ·011066 of a unit.
2. Consumption of zinc per hour $535{\cdot}25 \times \frac{1}{100} = 5{\cdot}3525$ grains.
3. Heat due to 5·3525 grains of zinc $110{\cdot}66 \times \frac{1}{100} = 1{\cdot}1066$ units.
4. Therefore the work per hour will (1·1066 − ·011066) 772 = 845·73 ft. lbs.
5. And the work per grain of zinc will be $\frac{845{\cdot}73}{5{\cdot}352} = 158$ or $\frac{99}{100}$ of the maximum duty.

When the velocity increases so that the current vanishes the duty = 159·6.

I. Let us now improve the engine by giving it a coil of 4 times the conductivity, which will be done by using a copper wire 389 feet long and $\frac{1}{8}$ of an inch diameter, the same battery being used as before. Then when the engine is kept still, we shall have a current 1·396 × 4 = 5·584, shown by a deflection of 79° 51′. Then we shall have

1. Heat evolved per hour by the wire $110{\cdot}65 \times \frac{4^2}{4} =$ 442·64 units.
2. Consumption of zinc per hour 535·25 × 4 = 2141 grains.
3. Heat due to 2141 grains 442·64 units.
4. Therefore the work per hour will be (442·64 − 442·64) 772=0.
5. And the work per grain of zinc will be $\frac{0}{2141}=0$

II. Start the engine with such a load as shall reduce the current to $\frac{2}{3}$, or to 3·7227 (74° 58′), then we shall have

1. Heat evolved per hour by the wire $442{\cdot}64 \times \left(\frac{2}{3}\right)^2 =$ 196·73 units.
2. Consumption of zinc per hour $2141 \times \frac{2}{3} = 1427{\cdot}3$ grains.
3. Heat due to 1427·3 grains $442{\cdot}64 \times \frac{2}{3} = 295{\cdot}09$ units.
4. Therefore the work per hour will be (295·09 − 196·73) 772 = 75934.

* From the Proceedings of the Manchester Literary and Philosophical Society.

5. And the work per grain of zinc will be $\frac{75934}{1427 \cdot 3} = 53 \cdot 2$ or $\frac{1}{3}$ of the maximum duty.

III. Lessen the load so that the velocity of the engine is increased until the current is reduced to one half its original amount, or 2·792 shown on the galvanometer by a deflection of 70° 18′. Then we shall have

1. Heat evolved per hour by the wire $442.64 \times \left(\frac{1}{2}\right)^2 =$ 110·66 units.
2. Consumption of zinc per hour $2141 \times \frac{1}{2} = 1070 \cdot 5$ grains.
3. Heat due to 1070·5 grains, $442 \cdot 64 \times \frac{1}{2} = 221 \cdot 32$ units.
4. Therefore the work per hour will be $(221 \cdot 32 - 110 \cdot 66)\ 772 = 85430$ ft. lbs.
5. And the work per grain of zinc will be $\frac{85429}{1070 \cdot 5} = 79 \cdot 8$ or $\frac{1}{2}$ the maximum duty.

IV. Let the load be further reduced until the velocity reduces the current to $\frac{1}{3}$, or to 1·8613 shown by a deflection of 61° 45′. Then we shall have

1. Heat evolved per hour by the wire $442 \cdot 64 \times \left(\frac{1}{3}\right)^2 =$ 49·182 units.
2. Consumption of zinc per hour $2141 \times \frac{1}{3} = 713 \cdot 66$ grains.
3. Heat due to 713·66 grains of zinc $442 \cdot 64 \times \frac{1}{3} = 147 \cdot 55$ units.
4. Therefore the work per hour will be $(147 \cdot 55 - 49 \cdot 182)\ 772 = 75940$ ft. lbs.
5. And the work per grain of zinc will be $\frac{75940}{713 \cdot 66} = 106 \cdot 4$ or $\frac{2}{3}$ of the maximum duty.

V. Let the load be still further reduced until, with the increased velocity, the current becomes reduced to $\frac{1}{100}$, or to ·05584 showing a deflection of 3° 12′. Then we shall have

1. Heat evolved per hour by the wire $442 \cdot 64 \times \left(\frac{1}{100}\right)^2$ = ·044264 of a unit.
2. Consumption of zinc per hour $2141 \times \frac{1}{100} = 21 \cdot 41$ grains.
3. Heat due to 21·41 grains of zinc $442 \cdot 64 \times \frac{1}{100} = 4 \cdot 4264$ units.
4. Therefore the work per hour will be $(4 \cdot 4264 - \cdot 04426)\ 772 = 3383$ ft. lbs.
5. And the work per grain of zinc will be $\frac{3383}{21 \cdot 41} = 158$ or $\frac{99}{100}$ of the maximum duty.

Now suppose that we still further improve our engine by making the stationary magnets twice as powerful. In this case all the figures will remain exactly the same as before, the only difference being that the engine will only require to go at half the velocity in order to reduce the current to the same fraction of its first quantity. The attraction will be doubled, but the velocity being halved no change will take place in the amount of work given out.

In all cases the maximum amount of work per hour is obtained when the engine is going at such a velocity as reduces the current to one half of its amount when the engine is held stationary; and in this case the duty per grain of zinc is one half of the theoretical maximum.

The same principles apply equally well when, instead of employing the machine as an engine evolving work, we do work on it by forcibly reversing the direction of its motion. Suppose for instance we urge it with this reverse velocity until the quantity of current is quadrupled, or becomes 22·386 indicated by a deflection 87° 26′. Then we shall have

1. Heat evolved per hour by the wire $442 \cdot 64 \times 4^2 =$ 7082·2 units.
2. Consumption of zinc per hour $2141 \times 4 = 8564$ grains.
3. Heat due to 8564 grains of zinc $442 \cdot 64 \times 4 = 1770 \cdot 56$ units.
4. Therefore the work per hour will be $(1770 \cdot 56 - 7082 \cdot 2)\ 772 = -4100432$ ft. lbs.
5. And the work per grain of zinc will be $\frac{-4100432}{8564} = -478 \cdot 8$ or -3 times the maximum working duty.

The principal reason why there has been greater scope for the improvenmt of the steam engine than for the electro-magnetic engine arises from the circumstance that in the formula $\frac{a-b}{a}$, applied to the steam engine by Thomson, in which a and b are the highest and lowest temperatures, these values are limited by practical difficulties. For a cannot easily be taken above $459° + 374° = 833°$ from absolute zero, since that temperature gives 12·425 atmospheres of pressure, nor can b be readily taken at less than the atmospheric temperature or $449° + 60° = 519°$. Also there is much difficulty in preventing the escape of heat; whereas the insulation of electricity presents no difficulty,

I had arrived at the theory of the electro-magnetic engine in 1840, in which year I published a paper in the 4th Vol. of Sturgeon's Annals, demonstrating that there is "no variation in economy, whatever the arrangement of the conducting metal, or whatever the size of the battery." The experiments of that paper indicate 36 ft. lbs. as the maximum duty for a grain of zinc in a Wollaston battery. Multiplying this by 4 to bring it to the intensity of a Daniell's battery, we obtain 144 foot lbs. Here, as in the experiments in the paper on Mechanical Powers of Electro-Magnetism, Steam, and Horses, the actual duty is less than the theoretic; which is owing partly to the pulsatory nature of the current, and partly also to induced currents giving out heat in the substance of the iron cores of the electro-magnets; although these last were obviated as far as possible by using annealed tubes with slits down their sides.

J. P. JOULE

OBJECT TEACHING AND SCIENCE IN AMERICA

THE following article, reprinted from the *Scientific American*, will give some idea of the spirit in which the teaching of science is being pursued in the United States:—

"The public are beginning to be awakened to the fact that technical education is *the* education they require, being in accordance with the conditions of modern civilisation; and it is admitted that such technical education must be based upon a foundation of natural knowledge. The principles of the natural sciences must then, for the future, form an essential part of popular education; the only questions are, how far and in what manner are these sciences to be introduced? Whatever is to be the amount taught, educators are agreed that the first steps in natural science, or, in other words, in systematising natural knowledge, are to be taken as early as possible. Early impressions are the deepest, and every child before its school days is already an untrained student of nature. The foundations of technical education should, therefore, be laid in the primary school; but whether commenced thus early or not, the method will always be the same. The child must be encouraged and guided in its natural habits of observing, and it must be led to systematise its observations, connecting them together by a chain of reasoning into groups of related ideas. This method is simply that known as "object teaching;" and you may as well try to fly without wings, or to teach geography without maps or globes, as to teach natural science without objects and diagrams. There is not a teacher, nowadays, but has heard of this object teaching; there are hundreds who have tried to utilise it; there are "colleges" in which it is professedly taught as a system; and yet there seems to be no method applied to the inculcation of natural science more misunderstood than this, and no teaching in our schools, at present, more utterly destitute of good results. Ninety-nine out of a hundred who talk so glibly of object teaching forget that it is merely a method—a method that has for its end to inculcate knowledge; that this knowledge to be inculcated is the essential part of the lesson; and that a *thorough acquaintance with the subject must precede any application of this mere method of instruction.* To stand up and give a lesson upon a cat, without knowing the first principles of natural history, is simply to go through a farcical parody; and authorities who have no better conception of the purposes of object teaching than this, set the cart before the horse; or, rather they never hitch on their should-be-useful animal at all, but ride off upon this hobby, leaving the load of knowledge it was meant to draw standing in the ruts—where it has been standing, as Prof. Huxley admirably puts it, ever since the days of ancient Rome.

"It has been recently advocated that every public school should be supplied with a collection of objects to illustrate the fundamental facts of natural science. By all means let it be so; but let the first use to which these are put be to instruct the teachers themselves in what they will have to teach. Let them learn what there is in each object of educational value, and what are its worthless characters; let them recognise that no object is complete in itself, but is merely a part of a vast whole, and that their office is to lead the child to recognise its most important relations to other objects. In building up the edifice of knowledge, they must not use every rough stone indiscriminately, but they must teach the little builders to chip off the useless angles of selected pieces, and so shape them that every stone shall, at its proper time, fit into its proper place. If this be not done, the most instructive objects in the world will not raise its single line of substantial structure, but will rest upon the minds of the pupils as an unarranged heap of meaningless facts—facts which will not even be long remembered; and it is as well that they should not be, because utterly useless, being unconsolidated by any cement of reason.

"We fear that no better end is attained by, or can be hoped for from, object-teaching in our public schools, until, as we have said, the teachers themselves are thoroughly educated in the principles of natural science. To accomplish this, however, the ear of these who rule the teachers must be gained; and we raise the question whether the representatives of science should not have a voice in the management of our public school system? As object-teaching is a mere handmaid of science, is of use only to give scientific habits of thought, and to convey a knowledge of scientific facts, and is worthless without science, the public should see that its introduction into our schools be carried on under the advice of scientific experts, who shall direct what is best to be taught, and advise with the adepts in teaching how such knowledge may best be imparted. As a journal having the interests of science and education at heart, desiring to see science soundly popularised, and the masses made acquainted with its technical value, we make this suggestion, and furthermore ask: Is there any man of scientific attainments in the present Board of Education? Is there any scientific authortiy upon its general staff? And how many teachers favourably known to and having the confidence of the really scientific portion of the community are engaged in giving scientific instruction in our public schools?"

*TRANSMISSION THROUGH PNEUMATIC TUBES**

THE writer having been employed in designing the extension of a pneumatic despatch line in which some heavy gradients were unavoidable, and it became necessary to ascertain by calculation the steepest gradient that could be employed so as to obtain a sufficient carrying capacity in the new section of the line under given conditions of engine power and of length. Almost every text-book and paper on the velocity of gases in pipes gave a different formula, and the author therefore found it necessary to attempt to construct a convenient expression for the speeds of carriers of given weight and friction, under various conditions of pressure, gradients, and dimensions of tube. The problem of a successful pneumatic system is simply this: To make a given quantity of air expand from one pressure to another in such a way as return a fair equivalent of the work expended in compressing it. It is obviously impossible to regain the full equivalent of the work, because the compression is attended with the liberation of heat, which is dissipated and practically lost. Therefore, in designing a pneumatic system, the first thing is to contrive means of compressing the air as economically as possible; and, in the second place, to get back the available mechanical effect stored up in the compressed air, irrespectively of the work employed in compressing and examining it. The writer considers that small pneumatic tubes may be worked more profitably than large ones. The great convenience of and practical facilities for working small letter-carrying tubes have been amply proved by the extensive systems already laid down in Paris, Berlin, London, and in other towns, as adjuncts to the telegraph services. Tubes of somewhat larger diameter would undoubtedly work satisfactorily. Even still larger tubes, if of moderate lengths, might also be found useful for a variety of special applications. But the author does not believe that a pneumatic line working through a long tunnel could, for passenger traffic, ever compete in point of economy with locomotive railways. A pneumatic railway is essentially a rope-railway. Its rope is elastic, it is true, but it is not light. Every yard run of it, in a tunnel large enough to carry passengers, would weigh more than ½ cwt. And it is a rope, too, which has to be moved against considerable friction, and in being compressed and moved wastes power by its liberation of heat. In a pneumatic tunnel, such as that proposed between England and France, in order to move a goods train of 250 tons through at the rate of twenty-five miles an hour, it would be necessary to employ simultaneously a pressure of 1½lb. per square inch at one end, and a vacuum of 1½lb. per square inch at the other. The mechanical effect obtained with these combined—pressure and vacuum—would be consumed as follows:—

In accelerating the air	29	millions of foot pounds.
In accelerating the train	12	
By friction of the air	5721	
By friction of the train	330	

The resistance of the air, therefore, upon the walls of the tunnel would alone amount to 93 per cent. of the total mechanical effect employable for the transmission; while the really useful work would be only about 5½ per cent. of it. And to compress and exhaust the air to supply these items of expenditure of mechanical effect, engines would have to exert over 2,000 horse power at each end during the transmission, even on the supposition that the blowing machinery returned an equivalent of mechanical effect such as has never yet been obtained. This would not be an economical way of burning coals.

ROBERT SABINE

* Abstract of a paper read at the Liverpool Meeting of the British Association.

SCIENTIFIC SERIALS

Silliman's Journal, January, 1871. The opening article in this number is by Prof. J. D. Dana, "On the Quaternary or Post-tertiary of the New Haven Region," in which he proves from numerous observations that the glacial era in this district was an era of glaciers and not of icebergs, many evidences of glacier action being visible in the form of broad furrows from eight to ten inches in depth, and extending for long distances on beds of trap and granite.—The second paper is by Prof. W. A. Norton, "On the Corona seen in Total Eclipses of the Sun." The author attributes this phenomena to a solar aurora, but the observations on the recent eclipse will probably induce him to modify his opinions; his arguments being based on the observations made during previous eclipses, when the corona was not made such a special object of investigation. He lays great stress on the long streamers as indications of auroral action, though it now appears that these streamers are not so decidedly of solar origin as was supposed.—In a letter to Dr. W. Gibbs, Mr. O. N. Rood gives a short account of some experiments to determine the duration of lightning flashes. A cardboard disc, with fifteen narrow and radial apertures, was caused to rotate very rapidly on a pin. Occasionally, during a flash, the slits in the cardboard were seen distinctly as if the disc were stationary, but more usually they were distinctly elongated. From the observations made it would seem that the duration of the flashes was about $\frac{1}{600}$ of a second. The accuracy of this result may perhaps be rendered doubtful from the fact that both Becquerel and Faraday have noticed that gases are rendered slightly phosphorescent by electrical discharges.—Dr. A. M. Mayer contributes an article "On the physical condition of a closed circuit contiguous to a permanent and constant Voltaic current; or, on the electrotonic state." The author commences by giving extracts from Faraday's investigations, in which he uses the term electro-tonic state to indicate the condition of a wire in which an electric wave has been induced by the proximity of a conductor through which a constant current was passing. He has endeavoured to obtain some clue of the condition of such a closed circuit by passing through it another electric wave of a constant intensity, and which he ingeniously generated by slipping a flat spiral from the end of a permanent magnet, as described in the number of this journal for November last. Currents thus obtained are found, by means of a delicate reflecting galvanometer, to be practically of the same intensity; for on repeating the experiment several times this produced deflections differing from one another to an extent not greater than 20". In this manner it was determined that a definite electric current, traversing a metallic circuit in proximity to another traversed by a powerful voltaic current, has the same intensity, whether passed in the same direction as the latter or in a direction opposed to it. The author thinks, however, that a diminution in the velocity of the current ensues, and he intends to continue his experiments in order to settle this question.—This paper is followed by an abstract of the "Programme for the Observation of Stars of the Ninth Magnitude, undertaken by the German Astronomical Society; an analysis of gahnite from Mine Hill, Franklin Furnace, New Jersey, by G. J. Brush; and an account of the Observations of the Meteors of November 13 and 14, 1870."—The next article is by Prof. J. Le Conte, "On some Phenomena of Binocular Vision," in continuation of some previous papers. For examining the effects produced on observing objects with both eyes, the author employs a white plane about twenty inches long and of any convenient width. A notch is cut at one end of the board to enable the operator to place the plane just below the level of the eyes, the notch fitting on the bridge of the nose. By sticking pins on different parts of the board and drawing lines between the pins and the eyes, the phenomena of vision can be investigated. The author points out that when things are looked at with both eyes, the eyes themselves seem to double, two of them combining to form a binocular eye in the middle which looks out between two noses, while the other two are on either side beyond the noses. This article is well worth perusal.—The next paper is by Sidney I. Smith, "On a Fossil Insect from the Carboniferous Formation of Indiana," and is illustrated by a woodcut representing a wing 2·54 inches long and 0·85 broad, found in the grit quarry near Paoli, Orange County, Indiana, in cutting the stone for making whetstones.—Observations on the Earthquake of October 20th in North-eastern America have been collected by Mr. A. C. Twining. The area of disturbance extended from New Brunswick in the East to the State of Iowa in the West, and from the lakes of the River St. Lawrence in the North to Cincinnati and Richmond, Va., in the opposite direction. The shock travelled from about E. 6° N. to about W. 6° S. at the rate of 160 miles in a minute.—The concluding article is by Professor A. E. Verrill, "On some imperfectly known and new Asceidians from New England."

Silliman's Journal, February, 1871. This number opens with a paper by Dr. A. M. Mayer, "On Observations on the Variation of the Magnetic Declination in connection with the Aurora of October 14, 1870, with Remarks on the physical connection between changes in area of disturbed solar surface and magnetic perturbations." The aurora was first noticed at 6.30 P.M. on October 14, and the magnetic observations commenced at 6.35 P.M. and were continued till 10 P.M. The mean declination being represented by 0°, at 6.35 P.M. the declination was 5′·70 W. and at 6.56 P.M. 18′·37 W. The magnet then rapidly moved towards the E., and at 7.46 the declination was 21′·94 E. The motion now became westerly, and at 7.57½ P.M. the reading was 32′·19 W. There was next a rapid easterly movement till 8.5½ P.M., when the reading was 10′·42 E., deep rough streamers flashing up in the N.N.W. There was another deviation to 4′·55 W. at 8.10 P.M., after which the needle passed to the east of the neutral line, and, after several oscillations, reached the maximum easterly deviation of 22′·52 E. at 9.10 P.M. The author makes daily observations of the spots on the sun, and remarks on the connection existing between their appearance and magnetic disturbances. He points out the necessity of establishing several stations, where daily photographs of the sun may be taken.—The next communication is the first part of a series of "Notes on Granite Rocks," by T. Sterry Hurst, LL.D., F.R.S. This paper is continued in the numbers of the Journal for March, and its extraction may perhaps be more conveniently deferred until the whole of it has appeared.—Mr. E. D. Cope contributes a short note on "Siredon Metamorphoses."—This is followed by a note by Professor G. B. Andrews, "On Lower Carboniferous Limestones in Ohio," and the conclusion of Professor Verrill's "Descriptions of Ascidians from New England."—This number also contains a "Memoir of Professor Graham, by Professor J. N. Cooke, and a "Description of the Auroral belt of October 24-25, as observed at New Haven.

SOCIETIES AND ACADEMIES

London

Royal Institution of Great Britain, April 3.—Mr. Warren De la Rue, F.R.S., vice-president, in the chair. Mr. William Cubitt, Mr. William Gould, Mr. Robert Hannah, Mr. John Henry Mackenzie, Rev. John Macnaught, M.A., Mr. Joseph Reynolds Masters, Mr. George Borwick Robertson, F.C.S., and Mr. George Wilson, were elected members of the Royal Institution. The special thanks of the members were returned for the following donation to "The Fund for the Promotion of Experimental Researches:"—Mr. T. Williams Helps (6th donation), 10*l*.

Entomological Society, April 3. Mr. A. R. Wallace, president, in the chair.—The Secretary exhibited drawings of Chinese Lepidoptera, beautifully executed by Mr. Holdsworth, of Shanghai.—Mr. F. Smith exhibited several examples of gynandromorphous Aculeata Hymenoptera, including *Anthophora acervorum*, *Andrena nitida*, *Nomada baccata*, and *Apis mellifica*, the latter combining the characters of male and workers. Mr. Lewis referred to the damage occasioned to books by *Lepisma saccharina*, which fed upon the paste of the bindings, and caused them to fall to pieces. Mr. Lewis also read a paper on the arrangement of British Lepidoptera, as adopted by various authors and compilers of catalogues, and he deprecated very strongly the constant changes in arrangement and nomenclature that are being made, the writers in many cases failing to give any reasons for such changes.

Anthropological Institute, April 3.—Sir John Lubbock, Bart., president, in the chair. Messrs. F. W. Rudler and Archibald Hamilton were elected members. Mr. Boyd Dawkins, read a paper "On the results obtained by the Settle Cave Exploration Committee." Victoria Cave, near Settle, in Yorkshire, is situated half-way up a cliff 200 feet high, and consists of a series of large chambers and passages, and has from time to time furnished to its explorer, Mr. Jackson, a remarkable collection of ornaments and implements of bronze, iron, and bone, along with pottery and broken remains of various animals, viz., red-deer, roebuck, pig, horse, sheep, goat, badger, fox, and dog. Fragments of Samian ware and coins of Trajan prove that the stratum in which they were discovered was accumulated subsequently to the Roman invasion. The numerous articles and bones were described in full detail. The author concluded that the cave was first inhabited by a barbarous Neolithic family, and, lastly, after a long interval, by Roman provincials, or possibly their descendants fleeing away from the arms of an invader.—A paper by Dr. Barnard Davis, F.R.S., was read, "On some recent Anatomical Writings bearing upon Anthropology, by Prof. Luigi Calori, of Bologna;" principally on the magnificent memoir of that anatomist, "Del Cervello, nei due tipi Brachicefalo e Dolicocefalo Italiani," lately published. That work is divided into four parts:—1. On the figure of the Brain in the two types. 2. The cerebral convolutions; their various aspect and their variety or anomalies. 3. On the weight of the brain in the two Italian types, brachycephalic and dolichocephalic. 4. On the extension of the cerebral superficies in the two Italian types. The second article goes into a thorough examination of the cerebral convolutions and the varieties they present.—Mr. A. L. Lewis contributes a paper "On the builders of the Megalithic Monuments of Britain." A special general meeting of the members of the Institute was held previously for the purpose of adopting the regulations proposed by the Council. Trustees of the Institute were elected, viz., Sir John Lubbock, Bart., president; J. W. Flower, treasurer; and the Rev. Dunbar J. Heath, M.A.

Zoological Society, April 4.—Mr. R. Hudson in the chair. Mr. W. Saville Kent read a paper on some new or little known Madrepores contained in the collection of the British Museum, amongst which were new species of the genera *Acanthocyathus*, *Flabellum*, *Stylaster*, and *Allopora*.—A communication was read from Surgeon Francis Day containing a series of notes on some of the rarer and less-known of the Siluroid fishes of India.—A communication was read from Mr. G. Stewardson Brady containing a review of the known *Cypridinidæ* of the European seas, together with a description of a new species of the genus *Philomedes*, proposed to be called *Ph. folinii*.—A communication was read from Dr. J. E. Gray containing additional notes on *Rhinoclemmys mexicana*, a Mexican Tortoise recently described by him in the Society's "Proceedings."—A second communication from Dr. Gray contained some additional notes on the genera *Eupleres* and *Galidia*, and a note on *Lemur ruber*, founded on specimens of these animals lately procured in Madagascar by Mr. Crossley.

Linnean Society, April 6.—Mr. G. Bentham, president, in the chair. The president read a paper on the styles and stigmas of Proteaceæ. In plants belonging to this order, the anthers mostly discharge their pollen before the expansion of the flower, as is also the case in Compositæ. In this latter order self-fertilisation is prevented by the fact that the stigmas are on the under face of the style branches which remain hermetically closed until after the opening of the flower. In Proteaceæ, on the other hand, the style is undivided, and the stigmatic surface is exposed even in the bud; and the contrivances to screen it from the action of the pollen of its own flower are very various. The observations have been made, with but few exceptions, on dried plants, and require confirming or rectifying by those who have the opportunity of examining the living plants. The anthers generally form, as in Compositæ, a closed tube surrounding the stigma, which is, however, usually if not always immature at the time of the extension of the pollen. That self-fertilisation seldom if ever takes place is shown by the fact that in no genus is the style more completely smothered with pollen than in *Banksia*, while there is none in which fecundated fruit is rarer. In *Petrophila* the stigmatic surface consists of the minute tip of the style, which is, however, completely protected while in the bud from the action of the pollen by the perianth segments. In one section of *Persoonia* the style is completely turned away from the anthers, and the stigmatic point is buried in a pouch prepared to receive it. The anther immediately over this pouch is sometimes destitute of pollen. In *Banksia* and *Grevillea* there appears to be no protection against self-fertilisation except the immaturity of the stigma. In *Conospermum* and *Synaphea* one anther in each flower has two perfect cells, separated by a connective; in the two lateral stamens there is one perfect and one abortive cell; and in the fourth there are two abortive cells, the cells are open cups; the perfect one of each lateral anther applied face to face with the adjoining cell of the double anther forms with it a closed globe in the bud, opening as the flower expands so as to let fall the pollen, the style projects far beyond with the stigmatic surface bent towards the upper perianth segment in the bud. In *Conospermum*, where the upper anther has two perfect cells, and the lowest is abortive, the style recurves elastically as the flower opens, so as to direct the stigma towards the abortive anther; in *Synaphea*, where the upper anther is abortive and the lowest perfect, the stigma is retained in its primitive position over the abortive anther by a strapshaped appendage proceeding from the rudiment of that anther and firmly attached to the lower margin of the stigmatic disc.—"On the Generic Nomenclature of Lepidoptera." By J. D. Crotch.

Chemical Society, March 30.—Prof. Williamson, F.R.S., president, in the chair. The president delivered the following address:—"Gentlemen, I feel much pleasure in congratulating you on the rapidly increasing prosperity of our society, and the enlargement which has taken place in its sphere of usefulness. For on the one hand the number of our fellows continues to show a most satisfactory increase, and on the other hand your Council has made arrangements for carrying out the system of monthly reports, which has been for some time in contemplation. It was hoped that the Chemical Society of Paris might, from the first, co-operate with us in the preparation of these monthly reports, but circumstances beyond their control have prevented the sister society from joining us in the beginning of this year. Deeming it undesirable to delay the commencement of the reports, your Council still look forward to the future co-operation of the Paris Society in their preparation. You are aware that the present available income of the society was not considered to be sufficient to defray the additional expense of writing and printing these reports, and I have the pleasure of informing you that contributions to the extent of 1,175*l*. have been promised by members of your body towards supplying the defect during the first five years of the appearance of the reports. The British Association has moreover granted us the sum of 100*l*. for this year in aid of the undertaking. We hope that in five years the funds of the society may have sufficiently increased to enable us to pay the whole expense of the reports, and that their publication will be valued by the members of our society, and promote the advancement of our science wherever the English language is read."

Edinburgh

Royal Physical Society, March 22.—Mr. W. C. Peach, President, in the chair. Note on Carbon, showing ligneous Structure in Coal (with illustrative diagrams). By Professor Duns.—Mr. A. Taylor exhibited some undescribed Fossils from the Gilmerton Coalfield.—Remarks on some Japanese Skulls. By Dr. John Kennedy.—On Successive Glacial Periods, caused by Changes in Physical Geography. By Mr. Andrew Taylor.—Mr. C. W. Peach exhibited and described a few Zoophytes and Algæ, gathered on the shores by Port Phillip, near Melbourne.—Mr. Peach had to enter on a new field, and unfortunately had no works either on Australian Zoophytes or Algæ, beyond Busk's excellent catalogue of the Zoophytes contained in the British Museum, and part of a paper of Professor Wyville Thomson on some from Australia. He therefore regretted that his paper would come before them in an imperfect state. He first noticed several species of *Catenicella*—large masses of all were exhibited, as well as small portions on black paper prepared for the microscope—showing how luxuriantly these delicate animals built up their lovely homes. This genus is found plentifully on the shores of Africa, New Zealand, and Australia, but not in British seas, evidently being confined to warmer climates. He also introduced to the members several species of *Salicornaria*, *Cellilaria*, *Menipea*, *Scrupocellaria*, *Ætua*, *Bicellaria*, *Retepora*, *Flustra*, *Lepralia*, *Cresia*, *Crisidia*, *Serialaria*—altogether more than twenty species.

Glasgow

Geological Society, February 2.—Mr. J. Young, V.P., in the chair.—Mr. Robert Craig read a paper "On the Boulders found in Cuttings on the Beith Branch Railway." The line of railway referred to runs nearly south-east from Beith. The striations upon the glaciated rock-surfaces of the district have a general bearing of nearly N.E. to S.W.; the line accordingly at its western terminus crosses them almost at right angles. The cuttings run nearly parallel to the southern termination of the range of trap hills which extends from Gleniffer to Beith, and at the distance of little more than a mile from it. The Carboniferous strata crop out along the southern boundary of this trap range, and consequently about a mile to the north of the railway. In the trap range four well-marked varieties of porphyrite occur, which, with the easily-distinguished beds of the Carboniferous limestone, gave the geologist an opportunity of classifying the boulders and tracing them to their source with an exactitude not always attainable. Mr. Craig then read a table giving the percentage of the different kinds of boulders found in eight cuttings proceeding eastward from Beith, and showed that the changes which were observable in them always corresponded with the rocks to the north-east of the cuttings. This strictly local character of the boulder-clay he thought was strong proof that it was due to land-ice—that, in fact, it had been taken up and deposited as the glacial "foot-board moraine." Droppings of sea-ice would have consisted much more largely of rocks from a distance. A small percentage of travelled rocks undoubtedly occurred in the boulder-clay of the district; and this, it must be noted, in all parts of the deposit—at bottom, middle, and top. These erratics he supposed to have been dropped from time to time through fissures and crevasses of the ice during its progress. From some sections in which he had followed the direction of the ice-stream, he found there was a change in the boulder-clay every three to five miles, less or more according to the roughness or evenness of the ground. He recommended a more minute examination and comparison of the boulder-clays of different localities than had yet been effected.

March 2.—Mr. John Young, vice-president, in the chair. Mr. E. A. Wünsch read a paper on a section of the northern shore of Arran, giving an account of some transported blocks of limestones which he had observed there during the previous summer. After describing the remarkable succession of deposits which had made that part of Arran classic ground for the geologist, he referred more particularly to a characteristic bed of limestone found near the Salt Pans, on the north-eastern shore of the island. This limestone is of a deep red colour, and is full of the shells of *Productæ*—especially *Producta latissima*—together with fragments of *Encrinites* and other organisms. The bed is very regularly jointed, and breaks up into beautiful cubical masses.—Mr. James Thomson read a paper on the occurrence of *Stigmaria stellata* (Eichwald) in the lower Carboniferous series, at Wildshaw, in the Upper Ward of Lanarkshire. He described the position of the strata in which these plant-remains had been found—in beds of fire-clay and indurated sandstone, capping those thin bands of limestone which characterise the lower members of the Carboniferous series in Scotland. The section presented at Wildshaw was as under :—6 ft. calcareous shale ; 3 ft. hard light greyish sandstone ; 2 ft. fire-clay, containing portions of *Stigmaria ;* 3 ft. highly indurated sandstone, or chertzite, into which the *Stigmaria* roots passed ; 11 ft. thin banded limestone, with partings of calcareous shale interstratified. Mr. Thomson mentioned that remains of this variety of *Stigmaria* were of comparatively rare occurrence in the Scottish coal fields—he had only found them in two other localities, and always in the same geological horizon. He pointed out that *Stigmaria* were now generally admitted to be the roots of the *Sigillaria*, but in this case he found them associated and in contact with what some authorities had called *Norea taxina* (?). The specimens on the table presented very distinct stellate markings which had surrounded the rootlets at the base of attachment.

BERLIN

Royal Prussian Academy of Science, August 11, 1870. —A paper was read by Dr. Hugo Kroeker, on the law of the exhaustion of muscles.—Prof. W. Peters communicated descriptions of some new reptiles and Batrachia, including *Hemidactylus muriceus* from Guinea, *Cercosaura glabella* from Brazil, forming the type of a new subgenus *Urosaura*, *Tropidolepisma striolatum*, from N.E. Australia, *Geophis annulatus* from South America (?) *Uriechis lineatus* from Guinea, forming the type of a new subgenus *Metopophis*, *Scaphiophis albopunctatus* from Guinea, the type of a new genus allied to *Zamenis*, and *Hoplocephalus frenatus* from N.E. Australia. The Batrachia described include the types of two new genera, namely, *Entomoglossus pustulatus* and *Cophomantis punctillata*, both from Brazil ; the other species are *Rana longirostris* from Guinea, *Cystignathus diplolistris*, *Hylodes Henselii*, and *H. rugulosus* from Brazil, *Arthroleptis dispar* from Prince's Island, and *Phyllobates verruculatus* from Mexico. Figures of most of the species accompany the paper. Prof. Braun presented a most elaborate memoir on the genera *Marsilia* and *Pilularia*, containing a tabular synopsis, and full synonymic and distributional revision of the species.

October 10.—The only scientific papers read were two on subjects connected with the higher mathematics, by MM. Kennmer and Schwarz.

November 3.—Prof. Gustav Rose communicated some notes on the fall of a meteorite at Murzuk, in Fezzan.

November 27.—Prof. Dove presented a paper on the annual distribution of rain in central Europe.

December 1.—M. Kummer read a memoir on a peculiarity of the unities of the complex numbers obtained from the roots of the equation $\alpha^{\lambda} = 1$; and M. Kronecker appended to this paper a further note on a part of the subject treated of by M. Kummer.

December 5.—Prof. Reichert read a continuation of his memoir on the Skeleton of the Vertebrata, relating principally to the Myxinoidæ, Leptocephalidæ, and Cartilaginous Ganoids, *Protopterus anguilliformis* and the *Chimæræ*.

December 15.—Prof. Roth read a paper on the Theory of Metamorphism and the production of the crystalline slates.—A memoir on the principal tangential curves of the Kummerian surface of the fourth degree, with sixteen nodal points, by Dr. F. Klein and Dr. S. Lie, was communicated by Prof. Kummer.

December 22.—Prof. W. Peters communicated a monographic revision of the Chiropterous genera *Nycteris* and *Atalapha*. The author reunites to the genus *Nycteris*, originally established by Geoffroy Saint Hilaire, the groups *Nycterops* and *Petalia*, which have been separated as distinct genera by Dr. Gray ; he also remarks that many unnecessary species have been established in it. He describes and gives the synonymy of 9 species and figures the typical form (*N. Hispida*) and the lower dentition of all of them. Two new species are described, namely *N. angolensis* and *N. damarensis*. The species of the genus *Atalapha*, which figure in the works of various authors under the genera *Scotophilus*, *Lasiurus*, and *Nycticejus*, are very difficult to discriminate satisfactorily ; Prof. Peters recognises 11, of which 3 are described as new, namely, *A. Frantzii*, *A pallescens*, and *A egregia*. All the species are American, and the type is *A noveboracensis*.

January 9 and 12, 1871.—M. Kronecker read two mathematical papers, of which no details are given.

January 19.—Prof. Ehrenberg communicated a review of the investigations made since 1847 on the abundant organic life borne invisibly by the atmosphere, as a supplement to his former memoirs on trade-wind, dust, and blood-rain. Since 1847 no less than 186 cases of the occurrence of these phenomena have been observed, and 42 samples have been submitted by the author to examination. He considers that the results of these investigations bear out his former conclusions.—In connection with this Prof. Dove communicated some observations on the "Föhn" observed at Trogen on the 13th February, 1870

VIENNA

Imperial Academy of Sciences, January 12.—Prof. Hlasiwetz communicated a memoir by Dr. E. von Sommaruga on naphthylpurpuric acid and its derivatives. This acid is produced from dinitronaphthole, by the action of cyanide of potassium ; it is incapable of its being isolated from its salts. When the latter are prepared in aqueous solution, a blue compound is formed simultaneously. This was first observed by Hlasiwetz, and the author named it indophane. In alcoholic solutions it is not produced.

January 19.—Prof. L. Pfaunden presented a memoir on the elementary deduction of the fundamental equation of the dynamical gas theory ; and Prof. A. Lieben communicated the result of an investigation made by himself in conjunction with M. Rossi, upon formaldhyde and its conversion into methylic-alcohol. The author found that the product of the dry distillation of formiate of lime (formaldehyde) was converted into methylic alcohol by nascent hydrogen.

February 3.—A paper on the barytes of the ferriferous Lower Silurian and Carboniferous of Bohemia, and on baryte in general, by M. R. Helmhacker, and one on the increase of curvature of an oblique section of a surface, by D. K. Exner were read.—Mr. Karl Fritsch presented a comparison of the time of the flowering of the plants of North America and Europe, from which it appears that the lines of simultaneous flowering lie 5°—10° further south in America than in Europe. Elevation seems to have comparatively little influence.—A note from M. Max Schaffner was read, describing a method of obtaining thallium on a large scale from the dust produced during the roasting of iron pyrites.—Prof. Brücke communicated a new method of separating dextrine and glycogen from animal fluids and tissues.—Prof. Stefan presented a memoir on the influence of heat on the refraction of light in solid bodies, containing a series of determinations of the refraction of rock-salt, sylvine (perchloride of potassium), alum, fluorspar, and glass, at temperatures of 12°—94° C. (53°·6—201°·2 F.). The refractive power of the first four bodies decreases uniformly, and for all parts of the spectrum, with the increase of temperature ; the refractive power of glass increases with the temperature, and the increase becomes greater in passing from the red to the violet end of the spectrum. The alterations calculated for the line *D*, and an elevation of temperature of 100° C are :—

Rock-salt	−0·00373
Sylvine	−0·00345
Alum	−0·00134
Fluorspar	−0·00123
Glass	+0·00023

M. K. von Littrow communicated a memoir by M. L. Schulhof, on the determination of the orbit of the planet (108) Hecuba.—Prof. Hlasiwetz briefly communicated the results of a nearly complete investigation of Liebig's Extract of Meat made in his laboratory by Dr. J. Weidler. This extract is found to contain a previously unknown nitrogenous compound, having the formula

$C_7 H_8 N_4 O_3$, and therefore most intimately allied to theobromine and caffeine.—M. Tschermak presented a paper containing observations on a meteoric iron from the desert of Atacama in Chili. It is a large shield-shaped mass, weighing 103 pounds, and when broken not only shows the usual figures after treatment with acid, but even before the application of acid thin lamellæ of triolite are recognisable, inserted parallel to the hexahedral surfaces and interrupting the octahedral texture. A similar phenomenon is presented by a meteoric iron from Jewell Hill, Madison County, North Carolina.

February 9.—A memoir by Prof. Linnemann, entitled "A Contribution to the further knowledge of Pinakone," was read, and its author claimed the priority in the discovery that formaldehyde is produced by the dry distillation of formiate of lime, and that from it methylic alcohol and other compounds may be obtained. A memoir on the employment of an electrometer for the stroboscopic determination of the elevation of notes, by M. A. von Obermayer, was read.—A paper by Prof. A. Weiss, on the structure and nature of the Diatomaceæ, was communicated. The author stated that the silica of the Diatomacean frustule polarises light, that the Diatomaceæ are composed of innumerable, minute, but perfectly individualised, cells, and that it is to these that the markings of the silicious shells are due.—Dr. E. Klein presented a memoir on the median germ lamella, and its relation to the development of the first blood-vessels and blood corpuscles in the embryo of the fowl, and communicated a paper on the finer nerves of the vaginal mucous membrane, by Dr. A. Chrschtschonovitsch of Kasan.—Dr. A. Schrauf presented a second series of his mineralogical observations, in which he noticed certain forms of crystals of gypsum, crystals of argentite, the properties and paragenetic relations of the Azorean azorite and pyrrhite, a new mineral from Leadhills, to which he gave the name of eosite, and the characters of vanadite, dechenite, and descloizite.—Dr. S. Stern read a memoir on the theory of the resonance of solid bodies, with reference to the accompanying vibration of the air; and Prof. Reuss presented the first of a series of memoirs by Dr. Manzoni, on Mediterranean Bryozoa. In this the author notices sixteen species (one *Hippothoa*, one *Membranipora*, and fourteen *Lepraliæ*).

February 16.—A memoir by Dr. U. R. von Jepharovich, on diaphorite and freieslebenite was read. The author stated that two species, one monoclinic, the other rhombic, have been included under the name of freieslebenite. Their composition is identical, but they differ in density. For the rhombic species he proposes the name of diaphorite.—A memoir was also read on the theory of gases by Prof. L. Boltzmann.—Prof. Reuss communicated a memoir on some fossil star-fishes from the Rhenish grauwacke, by Dr. S. Simonowitsch. Four new species were described, namely, *Asterias acuminatus*, *Aspidosoma petaloides*, and two species forming a new genus, *Xenaster*, *X. margaritatus* and *simplex*.—Prof. von Oppolzer reported upon the calculations undertaken by him for the re-discovery of the lost planet (62) Erato.—Prof. F. Simony made some remarks on the Lacustrine erosion of shore-rocks belonging to various limestone formations.

I. R. Geological Institution, March 28.—Theodor Petersen read a paper on "Cœruleolactin." By this name he designates a new phosphatic mineral, which has been found in the mine of Rindsberg, near Katzenellenbogen (Nassau), in a layer of brown iron ore. It must be placed between Kolaite and Wawellite. The specific gravity is 2·59, the hardness 5.—Variscite. This mineral described by Breithaupt from Plauin had never been analysed. Petersen determined its sp. gr. to be 2·408.—Diabase from Nassau. Exact inquiries have proved that diabase very often contains small quantities of metallic compounds, and is probably the original source of different strata of ores. The felspar in diabase is usually oligoclase, and not as had been generally supposed labradorite.—F. Karrer and Th. Fuchs on the "Relations between the different strata of the marine deposits of the Miocene Vienna Basin." From many new sections which they obtained along the aqueduct now in construction between Vienna and Gloggnitz, the authors endeavour to show that the clay of Baden and that of Geinfahrn, the sandstones of Pœtzleinsdorf, the limestones (leithakalk), &c., are not deposits of different geological ages, as had hitherto been generally supposed, but represent different facies of the same age, and like the zones of living organisms in the seas of our day, pass into each other without any exact limit.—M. F. Posepny spoke of the penetration of Klastic masses through eruptive or sedimentary rocks. The so-called Glam in the Transylvanian mining districts is an evident example of this phenomenon, and may be compared with the dowkies in N.W. England, and the Gangthonschiefer in the mines of the Harz. An exact study of the phenomenon showed that it originated from very different causes. Sometimes the klastic masses were formed by mechanical friction, in other cases they have been successively deposited by water, sometimes they are masses of mud and pebbles, which penetrated in open veins or cavities of the rock.

BOOKS RECEIVED

ENGLISH.—British Insects; their Form, Structure, and Habits: E. F. Staveley (L. Reeve and Co.).—On Intelligence: H. Paine, translated by T. D. Haye, part I. (L. Reeve and Co.)—The Bijou Gazetteer of the World: W. H. Rosser (Warne and Co.)

APE RESEMBLANCES TO MAN

THE Zoological Society can hardly fail to derive decided material advantage from the publication of Mr. Darwin's "Descent of Man." It has been said that already there is a perceptible increase in the visitors to the monkey-house, though an early spring has no doubt co-operated with scientific zeal in the promotion of pilgrimages to the Regent's Park, undertaken in the interest of a more than Chinese worship of ancestors. These visits would, perhaps, be considerably increased if it were very widely known that a fine specimen of a closely-related structural ally was there to be seen and heard, and one the resemblance of which to us has, I venture to think, not been generally appreciated sufficiently. I allude to the fine specimen of the Hoolock Gibbon which has been some time at the Gardens, and which appears to rejoice in good health, good temper, and good voice.

Differing so greatly and fundamentally as I do from Mr. Darwin, it is with sincere pleasure that I give my testimony to the correctness of his appreciation of the value and bearing of man's bodily structure on his zoological position. There can, I think, be no doubt that his frame is so closely related to that of the anthropoid division of the Old World apes, that to accord to it the rank of a family is to go to the extreme of maintainable distinction. Descending, however, to smaller divisions, it is generally taken for granted that the palm of resemblance to ourselves can be disputed by the Orang (Simia), or by the African genus Troglodytes (which includes both the Gorilla and Chimpanzee) alone. The third member, however, of the anthropoid Simian Graces—the genus Hylobates (long-armed apes or Gibbons)—has claims to advance for an award in its favour which I am disposed to consider not unworthy of consideration. Assuming, for argument's sake, the truth of Mr. Darwin's hypothesis that man's body was derived by natural generation from some form of ape, it may, I think, possibly be the case that we have in the existing Gibbon the representative of an ancestor more in the direct line than either the Orang or the African forms, and this in spite of the many points in which the Gibbon recedes yet further from human structure. For though it is indisputable that we can enumerate a greater number of points of resemblance between man and Simia or Troglodytes than between man and the Gibbons, while it would be easy to draw out a catalogue of details by which the last-named apes differ more from man than do Simia and Troglodytes, nevertheless there are certain points in which the Gibbon genus resembles Homo which are striking and perhaps significant. Although the enormous length of the arms disguises the resemblance, yet the proportions of the Gibbon's frame (as in some respects long ago pointed out by Professor Huxley) are singularly human. The length of the leg as compared with the trunk, and the form and proportion of the bony thorax, are points which may be mentioned. Again, a Gibbon (the Siamang) is the only ape which possesses that striking human feature—a true chin. The slight prominence of the nose too is also very remarkable, a point which has not escaped the notice of Mr. Darwin, and is to be seen in the living specimen here referred to. Again, the power, quality, and compass of the voice are qualities justly dwelt upon by the last-named author; and, finally, the gentle, yet quick and active nature of the Gibbon is eminently noteworthy.

On the other hand the Orang is a very specially organised, quite aberrant beast (as I have elsewhere endeavoured to show), and the brain in the genus Troglodytes is considered by Gratiolet to indicate altogether other relationships. Now it is not impossible, on the hypothesis assumed, that the Orang, Gorilla, and Chimpanzee may be types which have really diverged further from that anthropoid root-form which most nearly resembled man than has the Gibbon, and that adaptations to conditions may have superinduced many of those human resemblances which at present characterise them. It seems difficult, certainly, to apply this view to some details, such *e.g.* as the vaginal process of the temporal bone on the basis cranii. On the other hand, it is not in the highest but in one of the lowest of the Simiadæ that I have found an anchylosed styloid process to be occasionally present.

A very interesting fact is the great Miocene Gibbon of Europe, the Dryopithecus, which goes to confirm the view here suggested as to the dignity of Hylobates; but of course we can but speculate inconclusively till Palæontology furnishes us with the nearest extinct representatives of the Gorilla, Chimpanzee, and Orang.

To prevent misconception, I may add that fully recognising the truth of Mr. Darwin's appreciation of man's zoological position, which I have ever maintained and indeed laboured to support, I none the less completely differ from him when I include the totality of man's being. So considered, Science convinces me that a monkey and a mushroom differ less from each other than do a monkey and a man.

ST. GEORGE MIVART

THE COLLECTION OF INVERTEBRATE ANIMALS IN THE FREE PUBLIC MUSEUM, LIVERPOOL

II.

WE have mentioned in a previous article * the division of the series of Invertebrate Animals in the Liverpool Museum into 216 groups. The following is the plan of arrangement adopted in connection with each group.

Wherever circumstances permit the plan includes: (1) A printed schedule. (2) Exotic species. (3) British representatives. (4) The printed tablet. (5) Earliest fossils. (6) Diagrams and other illustrations. (7) Species and varieties on a more extended scale.

(1) The schedule, of which an example follows, is printed in large type, and is placed conspicuously at the head of the drawer; it is designed to show the derivation of the group, *e.g.*—

"Group 198.

SUB-KINGDOM—*Annulosa*, Skeleton external, ringed.
PROVINCE—*Arthropoda*, Limbs jointed.
CLASS—*Insecta*, Legs six.
SUB-CLASS—*Metabola*, Transformations complete.
ORDER—*Lepidoptera*, Wings with scales.

* See NATURE, vol. iii. p. 202.

SUB-ORDER—*Rhopalocera*, Horns clubbed at the apex.
FAMILY—*Papilionidæ*, Middle nerve of fore-wing four-branched."

The next sub-division appears on the tablet as the distinctive title of the 198th group.

"GENUS—*Ornithoptera* and allies, Bird-winged butterflies. About twenty species known."

(2) The further portion of the drawer, to the extent of three-fifths (more or less) of the whole area, accommodates from ten to sixty exotic species; such as are most distinct being preferred. A reference to the authority accompanies many of the generic, sub-generic, and specific names. The locality, when copied from a monograph, is stated simply; but when it is known where the specimen has been collected, the word "from" is added—*e.g.* "from Madagascar."

(3) The nearer right-hand corner of the drawer is occupied by representatives of the group indigenous to Britain. Some groups have no British representatives; in others—*e.g. Noctuæ genuinæ*, a selection from the British species fills three-fourths of the drawer. Amongst these, foreign specimens of rarities are admitted, but in all such cases the words "exotic specimen" are appended to the name on the label.

(4) The nearer left-hand corner is assigned to a few fossils showing the earliest appearance of the group in the Geological record. In one or two instances, *e.g. Hippurites*, the entire group is fossil, in others, of course, fossils are absent.

(5) Between these two latter sections of the drawer is placed the printed tablet, about the size of an octavo page. It exhibits an attempt to describe some of the salient points in the life-history of the group. Here, and throughout the series, some attention has been given to ensure legibility; names and descriptions being of much less value when they cannot be read easily.

(6) The upright portion of the table case over each drawer is given to miscellaneous illustrations of the group. The series includes drawings and photographs of structure and anatomy, economic products, silk in various stages, marine and freshwater pearls, cameos, from the rough medallion cut from the shell to the finished work, polished shells, and sections showing the interior of shells, eggs, preserved larvæ and pupæ, preparations in spirits, examples of mimicry, nests of *Hymenoptera*, galls and their tenants, timber and stone pierced by molluscs, crustacea and insects, distorted growths, healed fractures, coral beads, British and exotic specimens of fungi growing on pupæ, and many other objects of interest.

(7) The blocks on which some of the table cases rest are fitted with drawers suitable for receiving an extended series of species and varieties, valuable only to the student, and intended to be seen only on application to the Curator. Very little progress has been made in carrying out this portion of the plan, which has, however, the good effect of rendering it quite needless to overcrowd the groups with insignificant species.

The difficulties attending the formation of the series of specimens have not been very great. Collections have been presented to the Museum by several friends of natural science, amongst whom may be mentioned Mr. Samuel Smith, of Liverpool, the donor of a collection of shells rich in generic forms and in costly rarities of the highest beauty. Mr. Moore has been successful in establishing friendly communications with many captains of merchant vessels sailing from the port of Liverpool, some of whom have been supplied by the committee with dredges and collecting apparatus, and have become enthusiastic naturalists. In recognition of their services several of them have been received as Associate Members of the Literary and Philosophical Society of Liverpool, a distinction which seems to be highly appreciated by them. Something has also been done in the way of exchanges; but a large proportion of the whole series has been purchased specimen by specimen. No object has been purchased simply on account of its rarity, but at the same time no reasonable expense has been spared in procuring the most beautiful and perfect examples.

A few general remarks on the subject of expense may be permitted: details will gladly be communicated to inquirers connected with museums. Few collections exhibited to the public will bear comparison with corresponding series contained in private cabinets. Why should this any longer be permitted? It may arise, *in part*, from the impression that in public museums it is unnecessary to spend much on specimens. There can be no excuse for extravagance, but economy may be pushed too far. The trouble and great risk of collecting in tropical climates must often be very inadequately represented by the apparently high prices asked for the chief desiderata, and the rest of a collector's stock may remain on his hands for years. Again, if a genus or a group is illustrated in nature by a great variety of beautiful forms, this surely is a biological fact which may claim, on scientific grounds, to be fairly and appropriately represented. Even on the most severe estimate of what is necessary for an educational series, something must be allowed simply for the sake of beauty and attractiveness; that is to say, if museums are to avoid the fate of certain parochial lending libraries which contain only such books as everybody *ought* to like to read. Naturalists of the very highest scientific standing, much more ordinary observers, are greatly under the influence of beauty of form and colour. Even Mr. Wallace himself would not have been so near syncope at the sight of a new Brachelytron as he seems to have been on his first introduction to the magnificent *O. Crœsus.* Why, moreover, should the public be taught to esteem art treasures as so much more valuable than the choicest productions of nature? One hears of a pair of vases being sold for 2,000*l.*, a sum which would provide twenty first-rate table cases, and stock them with very fair illustrations of the whole of the invertebrate groups. It is a happy circumstance that a museum of common objects may, at a trifling cost, be established in almost any village, and with judicious local influence brought to bear upon it, may prove both useful and creditable; but why should not wealthy communities, possessing endless drawing-rooms ablaze with costly decorations, exercise something of a corresponding liberality towards the museum which is the representative of their appreciation of that which is higher than the highest art?

Considerable difficulty has been found in selecting appropriate materials for the printed tablets. Many of the chief continental authorities on the Invertebrata, admirable as are their works for the purpose of identifying species, afford scarcely a line of information on the life history of the objects they so grandly figure and often so elaborately describe. Even the reports of scientific expeditions may frequently be searched in vain for this kind of information, which has to be gleaned from authorities not always trustworthy, from scattered papers, or from books of travel such as have been issued in this country on the Malay Archipelago and the River Amazon. It is mortifying to exhibit forms distinguished by extraordinary developments of structure, and to be able to say nothing on associated habits. Such strange developments were once considered to be mere freaks of nature, but no one now doubts their having a biological and even a genealogical significance. What a field is is here opened! How little of the biology of a new form has been exhausted when it has been collected, named, described, figured, and even dissected! Scientific treatises have prepared the foundation for a solid knowledge of the subject, but there would be occasion for regret if biology should ever come to be regarded by students in an aspect too exclusively histological or even physiological, if such a view operated to the prejudice of genuine out-of-door observations. The greatest advance in Natural History made in the present, or perhaps in any other generation, has been mainly accomplished by two observers who are pre-eminently life-historians.

Little need be said of the miscellaneous illustrations contained in the upright portion of the table-cases. They seem to be very successful in engaging the attention of visitors of all classes—a point which is felt to be of prominent importance where the admissions amount to about 2,000 daily. What brings them here? is a question which again and again suggests itself. Reduce the number by all the idlers and sight-seers who, no doubt, constitute a large proportion of the gathering; still, if only 100 or even 50 seek some kind of instruction, even these in the course of a year form a large and teachable class. As a firm believer in the humanising effect of an intelligent interest in Natural Science, to myself the grand museum problem seems to be, how to make such an institution most beneficial to the greatest number.

HENRY H. HIGGINS

PRE-EUCLIDIAN GEOMETRY

Die Geometrie und die Geometer vor Euklides. Von Prof. C. A. Bretschneider. (Leipzig: B. G. Teubner, 1870. London: Williams and Norgate.)

UNTIL the appearance of this book, Montucla's celebrated "History of Mathematics" contained almost all that was known about the early history of Mathematics up to the present time. Later historians, even the careful Chasles, have almost exclusively copied him, without taking the trouble of searching the Greek writings for themselves. Montucla's remarks, however, are not only meagre, they are even not always correct. For this reason Prof. Bretschneider has collected all important passages in Greek writings which refer to the state of Geometry in Greece in the time before Euclid. This author is the first of whom complete works have reached us; with him, therefore, a *History* of Geometry begins. With regard to the ante-Euclidian times we cannot advance beyond conjectures, and these will always depend more or less upon the individuality of the historian. Perfectly aware of this, Prof. Bretschneider gives in the little volume before us, of about 180 pages, not merely his conclusions, but he adds the whole material which he has collected. Instead of simply referring to an author, he quotes *in extenso* the original Greek text, and adds translations. Thus every reader is at once enabled to form his own opinion, which, we feel assured, will in most cases agree with that of our author.

In the first section Prof. Bretschneider considers the Geometry of the Ægyptians, and tries to make out how far their knowledge extended. He protests against the old opinion that they possessed only the very first notions of geometry, and that the Greeks did not obtain anything from them worthy of the name of science. He refutes equally strongly the statement of some modern writers, who maintain that the Ægyptians knew not only all that Euclid gives in his Elements, but were even acquainted with the theories of quadratic equations and of conic sections. According to him geometry originated in Ægypt, where it was cultivated for practical purposes. It was rather an *art* of mechanical drawing than a science proper. The results obtained were collected in the form of fixed rules, always ready for use, most of them probably strictly proved others perhaps resting on experience only. Those collections of rules were at an early age included in the religious canons. Any alteration, any improvement, was thus almost impossible, especially as the only cultivators of Science, the priests, would take a secondary interest only in anything not strictly connected with religion. Thus it is not to be wondered at that geometry remained for thousands of years in the same state, till the unfettered genius of the Greek nation began to cultivate it, and then the progress was a most rapid one.

It is, however, remarkable, although natural enough, that the Greeks retained to a certain extent the *form* into which Ægyptian priests had cast their propositions. For this fact there exists a testimony in a papyrus at the British Museum, formerly in the possession of the late Mr. Rhind, which contains a pretty complete treatise on Applied Mathematics, in the shape of problems which are stated in that peculiar form with which we are so well acquainted through Euclid's Elements. Dr. Birch, who has given an account of it, dates it as far back as 3400—3200 B.C. Prof. Bretschneider traces many other peculiarities in Euclid's Elements—for instance, the order of propositions—back to the same source; so that the Ægyptian priests, who lived about 6000 years ago, have, in the most direct manner, influenced the mode of teaching geometry in English schools even at the present time.

The extent of Ægyptian Geometry is estimated as follows:—the theory of angles and parallel lines; the construction of triangles, parallelograms, and trapezoids from given parts, and the determination of their areas; the elementary propositions of the circle together with the inscribed regular polygons;—this is about the sum total of Plane Geometry. In Solid Geometry their knowledge was limited to the first notions about lines perpendicular to a plane, and the theory of parallel lines and planes in space. They were acquainted with the existence of prisms, regular pyramids of four sides, of the right cone and cylinder, the sphere, and of the regular solids with the exception of the dodecahedron, which is the only one discovered by Pythagoras. Of the properties of these solids they knew little, the theory of the sphere alone appears developed to a certain degree necessary for astronomical purposes. Of proportions and similar figures they knew nothing.

The succeeding chapters relate to Geometry in Greece. We shall only mention a few of the most striking differences between Prof. Bretschneider and his predecessors. That most of the anecdotes about Pythagoras—his long captivity in Babylon, for instance,—are rejected, need scarcely be mentioned. But many readers will be surprised to hear that Plato is not considered a very eminent mathematician as he himself did almost nothing to enrich this science, and most of the theorems usually believed to be due to Plato are his pupils'. Thus the conic sections were invented by Menaichmos. Again, the *reductio ad absurdum* is considered one of the simplest methods of demonstration and used long before Euclid thought of it.

One of the most important points in the book consists in a long passage out of Eudemos' "History of Mathematics" (about 340 B.C.), which Bretschneider was fortunate enough to discover in the commentary on Aristotle by Simplikios. It contains a critique on investigations on the problem of squaring the circle. Some of the methods here employed are exceedingly interesting, as they show what means were at the disposal of the mathematician. Antiphon, a contemporary of Socrates, inscribes a regular polygon in a circle, and then proceeds in the well-known manner to double the number of sides till these at last coincide with the circumference of the circle. He then considers the circle as a regular polygon, and says that it may be converted, like any other polygon, into a square. It appears, therefore, that Antiphon was the first who introduced infinitesimals into geometry, and thus became the forerunner of Archimedes. These methods were, however, far too much in advance of his time, and Eudemos rejects them as not exact. Hippocrates, known by his quadrature of the lunulæ, makes several attempts to extend this discovery, and to obtain similar results for other lunulæ and thence for the whole circle. Some of these attempts indicate great power, although they lead to nothing tangible.

The book contains many other important results, and all those who take an interest in the history of the development of science will feel indebted to the author for its publication.

OUR BOOK SHELF

Notes on the Natural History of the Strait of Magellan and West Coast of Patagonia, made during the Voyage of H.M.S. "Nassau," in the years 1866—1869. By Robert O. Cunningham, M.D., F.Z.S., &c., Naturalist to the Expedition. (Edinburgh: Edmonston and Douglas.)

WE regret to be obliged to find fault with the work of a naturalist, but duty to our readers compels us to say that this book should never have been published. There is perhaps no part of the world which is at once so remote and inhabited by such interesting savage tribes, with the main features of whose scenery and natural productions the public is so well informed as that which forms the subject of this book. It is therefore surprising that a gentleman who has had the opportunity of studying the natural history of this region at his leisure, should have thought himself justified in printing a volume of 500 pages of his rough journal, nine-tenths of which are occupied with a bald record of the usual monotonous incidents of sea and shore excursions, and with repetitions of facts already given us by Darwin, Hooker, and a host of other less eminent writers. There are, of course, some interesting facts and some original observations in this volume, but they are so thinly scattered amid a mass of details of weather and personal incidents, with records of the gathering of every common plant and the capture of every common as well as uncommon bird or insect, as to be not worth the search after. The book too is got up with an utter disregard of the reader's convenience. The author journalises his whole voyage, and at least one third of the volume treats of other parts of the world than those indicated by the title, yet the heading throughout is "Strait of Magellan," even when Rio Janeiro, Valparaiso, or the Azores are being described. Neither is there any indication of years or months, except when a change occurs; and if we find that something was captured on the "14th," we have to go back or forward many pages to discover whether we are in May or December. The plates too are wholly without references to the letterpress; and we find a curious plant (*Philesia buxifolia*) described at page 173, and figured at page 321, with no reference from description to figure or from figure to description. The illustrations seem thrown in at random, anything the author collected being apparently deemed worthy of a plate. On no other principle can we explain the plate devoted to an indifferent figure of the cranium of so common an animal as the puma; and another to the furcula of a condor, the picking-up of which is recorded at page 113, and figured full size, *à propos* of nothing, at page 303.

It is the more to be regretted that such a book as this has been published, because there is ample room for one of a different character, and for which Dr. Cunningham must have collected or have been able to obtain ample materials. The temperate parts of South America form a well-marked district, the productions of which are exceedingly interesting and their affinities well worthy of careful study. The relations of the fauna and flora of this district to those of Tropical America, of Europe, of Australia, and of New Zealand, require a thorough and critical examination; and this could hardly fail to throw much light on the means by which organic forms have been distributed, and on the relative importance of the various zoological regions into which the globe has been divided.

The author states in his preface that he has not yet completed the examination of his materials. Why then did he rush into print before he was able to lay before the world a single generalised result of his three years' voyage? W.

Les Houillères en 1869. Par Amédée Burat, Secrétaire du Comité des Houillères Françaises. Texte et Atlas. (Paris, 1870. London: Williams and Norgate.)

THIS is an annual publication of a semi-official character, proceeding from M. Burat, the Secretary of the very useful Association of Coal-mine Proprietors in France. We are not aware that any such committee of coal owners exists in Great Britain, although other trades or professions, such as bankers, railway companies, &c., have similar committees. The Iron and Steel Institute, which has lately been holding its meeting in London, fulfils to some extent this purpose in regard to the iron trade. Wherever such associations exist we wish that they could be persuaded to publish as complete and valuable reports on the condition of their branch of trade as we have in these annual reports on the French coal trade, now available for ten or eleven years back. The present report consists of four chapters, which treat respectively of the strikes of the coal-miners, which had greatly interfered with the trade, improvements in the machinery and modes of working coal mines, the statistical conditions of the production of coal in 1860, and the legislation which had taken place in relation to the trade. It is impossible to avoid feeling, however, that the interest of such a complete statement is much reduced by the events which have occurred since the year to which it relates. All industrial improvement in France must be greatly retarded, if not converted into retrogression, for some time to come. The remarks on the subject of strikes form perhaps the most interesting part of the volume. England is the birth-place of trades' unions, and our capitalists feel their influence severely; but it is among an unstable and disaffected population, like that of the French manufacturing and mining districts, that they produce really evil effects. M. Burat gives emphatic testimony to the high character of British workmen, wholly uneducated as they often are. He says (p. 135), "Once again, in traversing the coal fields of England, we have been struck with their superiority, due not only to the special conditions of the coal basins, but to the aptitudes and the discipline of their working population."

W. S. J.

Jahresbericht uber die Fortschritte der Chemie, und verwandter Theile anderer Wissenschaften. Herausgegeben von Adolph Strecker, für 1868. (Giessen, 1870. London: Williams and Norgate.)

THE Jahresbericht is too well known as a trustworthy book of reference, both for chemists and physicists, to need commendation; and the care and judgment with which it is compiled have made it almost indispensable to those interested in science. In these days, when the amount of work done—both useful and useless—is so great, it is no slight convenience to have the year's labour carefully sifted and preserved for reference in a single volume. The present volume, under the editorship of Herr Adolph Strecker, is arranged with all the care which has characterised previous numbers, and contains numerous papers of unusual importance. Among the most important of these may be noted Becquerel's researches on electro-chemical action, Graham's experiments on the occlusion of hydrogen by palladium, and the existence of the metal hydrogenium. Rammelsberg's researches on the periodates are given at considerable length, and also Bunsen's process for separating the platinum metals found in the residues of the Russian mint. In the organic section of the book very important papers are given on the constitution and derivation of benzol, toluol, and napthalin, and Gräbe and Liebermann's valuable researches on the preparation of alizarin from anthracene are fully described. Perhaps the success of the Jahresbericht has caused the Chemical Society to make the changes in their journal which, we understand, are in contemplation. We believe that it is intended to reproduce in the pages of the new journal all important researches made in this country and abroad, so that it will become to us what the Jahresbericht already is to Germany. If the same care is bestowed on its production that has always characterised its German contemporary, we anticipate for it a similar and deserved success.

F. J.

Notes or Jottings about Aldeburgh, Suffolk. Relating to Matters Historical, Antiquarian, Ornithological, and Entomological. By Nicholas Fenwick Hele, Surgeon. 8vo, pp. 198. (London, 1870.)

IT is no disparagement to Mr. Hele to say that he is not a Gilbert White, and the reviewers who have compared this book with the "Natural History and Antiquities of Selborne" have certainly done its author a wrong, while they have shown their own want of discrimination. Gilbert White was in the front rank of the naturalists and antiquarians of his day; as an outdoor observer he had no equal, and perhaps never will have one. Add to this the charming and delicate simplicity of his ideas, rendered all the more striking by the slight shade of pedantry which not ungracefully tinges his style; for the old pupil of Warton never forgot his scholarly breeding, and what wonder is there that "Selborne" is an English classic? If ever there was a naturalist in whom the poetic faculty was developed, if ever there was one who wittingly or unwittingly possessed the scientific use of the imagination, Gilbert White was the man. Now, there is nothing to show that Mr. Hele is a closer observer than (happily) many of his fellows, and what he has to say he says in very plain, straightforward language. It is clear that he keeps his eyes open whene'er he takes his walks abroad, but he favours us with few inferences from his own experience. Still we must particularly praise the absence of any attempt at fine writing, and the consequence is a little volume of a kind of which we should be glad to see many more. The "matters historical and antiquarian" of which he treats are, of course, beside the path of Nature, though the old boat found in company with flint-flakes deserves the attention of the Anthropological Institute; but the topographical, ornithological, and entomological notes include much that is of interest, exception being taken perhaps to a few of the statements. However, Mr. Hele's opening assertion that "Aldeburgh, as a place of resort for the naturalist, may be fairly classed as one of the most attractive localities in the east of England," is undoubtedly true, and his sketch of the neighbourhood shows that he appreciates its advantages. We have derived great pleasure from this unpretending little volume, and are sure most of our readers will do the same.

Mineralogie der Vulcane. Von G. Landgrebe. (Cassel and Leipzig, 1870. London: Williams and Norgate.)

THIS is not a very satisfactory book. It consists of an alphabetical arrangement of minerals with a brief description of each species, the species selected being those which the author regards as volcanic minerals. In spite of his title of "member of several learned societies," we take leave to doubt whether he has any clear idea of what a volcanic mineral is. A great part of his book is devoted to minerals which, like the zeolites, are not original volcanic products, but the result of subsequent changes. Any mineral which he can discover to have been ever found in an eruptive rock, he sets down in his pages as one of the "minerals of volcanoes." There is no critical faculty shown in discriminating between the primary and secondary ingredients in volcanic rocks. A good work on volcanic minerals properly so called, with a minute and exhaustive examination of their microscopic structure, and a philosophic induction therefrom as to some of the conditions under which volcanic action must take place, would be a great boon to science. But it is not to Dr. Landgrebe that we must look for such a treatise. He tells us that perhaps he might have delayed the publication of his volume until he could take advantage of the results which the new development of mineralogy through the application of the microscope promises to furnish; but as he found the delay might prove a tedious one, he decided not to wait any longer, but to present his labour of "Lust und Liebe" to the indulgent criticism of the public. Even so; such is the history of too many books in the scientific as well as in other branches of literature.

A. G.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Science College at Newcastle

PERMIT me to rectify a misapprehension which appears, not through any fault or oversight on your part, in your appreciative article upon the College of Physical Science, which the University of Durham, with the co-operation of the scientific men of the North of England, is engaged in founding at Newcastle-upon-Tyne.

The Executive Committee fully recognises the importance of Biology. The professorial chair, which was called at the public meeting that of Geology and Mineralogy, will be called, according to a subsequent decision of the committee, the Chair of Geology, Biology, and Mineralogy. It is true that this designation leaves it uncertain whether Biology is co-ordinated with Geology, and has its claim to be a distinct science allowed, or is subordinated and intended to be treated only as a component part of Geology. In the former case, it may be said, the Chair will be too capacious for one man to fill; in the latter, the rights of biology are but inadequately acknowledged.

The answer to this is, that the programme of teaching is necessarily, at the present stage of affairs, initiatory. It will, no doubt, when the work of the Institution has commenced, and the scale of operations which everything seems to foreshadow has been in some measure realised, receive such expansions and modifications as are suitable to the relative value of the sciences, and the actual wants of the students. University College, Durham, April 17

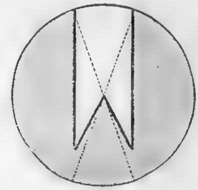
The Aurora Borealis

A VERY bright display of aurora was visible here last night, illuminating the greater part of the heavens at intervals with a fitful light. At 9h. 45m., when I first noticed it, broad cirrus-like brushes of white light stretched in parallel bands across the zenith, from below Corona in the north-east, across Cor Caroli, nearly overhead, to about the altitude, and 15° or 20° south of Venus, then shining dimly through clouds in the western sky. My view of the aurora was afterwards confined to an east window; but from a short examination of a clear part of the sky towards south-west, it appeared to be almost as bright, at first, in the opposite direction as in the quarter between north and east, where I had, from that time onwards, an uninterrupted view of its progress. The streamers were white, and irregular in form, rising from no distinct arch, or definite base in any quarter, but they occasionally met and formed a bright corona overhead. A rose-tint pervaded some of them, in the north-east, at 10h. 30m., and presented itself in different parts of the sky until about 11h., when the phenomenon faded, and a faint glow only remained visible in the north. At about 11h. 40m., while streamers reappeared, forming a bright corona overhead, whose arcs and beams appeared to grow more densely luminous until 12h. 15m. It then showed a well-defined central nucleus, with rays of great brightness proceeding from it, about three-sevenths of the distance from η Ursæ Majoris to Arcturus, white streamers rising to meet it all round, with the appearance of a cupola or dome. While I watched some of the brighter stars through its dense light-cloud, it rapidly assumed a vivid fiery red colour, and a similar bright appearance breaking out at the same moment at the base of a north-east streamer, the fiery glow reflected among the clouds in that direction perfectly resembled a distant conflagration. A wide expanse of brilliant orange and crimson-red light soon joined these two regions of greatest intensity together in one splendid blaze of ruddy colours. This brilliant outburst faded away at 12h. 25m., the streamers disappearing, until 12h. 40m., when they again met overhead, and formed a corona with a sharply-defined nucleus, about 3° west of the star γ Böotis. The light of the white streamers flickered considerably, as if waves of varying brightness were driven rapidly over the whole phenomenon by the wind. Until after two o'clock, when the moon rose, and their light was weakened although not extinguished, a constant succession of bright steamers occupied the north-east sky between the horizon and the zenith; towards these I directed the slit of a Browning's Student's Spectroscope, in order to determine, if possible, the position of some of the auroral lines. A single greenish line only was so faintly visible in the spectroscope that all attempts to view it simultaneously with the cross-wires of the instrument proved unsuccessful. A simple form of pointer, substituted for the use of the wires in the dark field of the telescope enabled me, however, to identify its position with considerable accuracy.

A circular card, of the figure shown in the sketch, was slipped into the forward end of the eye-piece until it reached the diaphragm upon which the cross wires are stretched. It was so disposed that the angular pointer in the middle of the card exactly filled up the lower angle of the cross-wires; and its sharp point coincides almost exactly with the place of their intersection. In a field of view almost dark it was possible to see the summit of the card-pointer with considerable distinctness; and if a great and imposing phenomenon may be compared with an object so diminutive, the appearance of its dark peak, surmounted by the narrow, flickering line of light, resembled in the dim field of view the cone of a volcano, projecting in a thin



jet from its apex frequent eruptions of varying height and brightness. By obtaining a reading of the soda-line seen in the flame of a salted spirit lamp, and referred to the pointer in the same manner, I obtained as a result of three observations of the auroral line, differing less than two minutes on the graduated position-circle of the spectroscope, a place in the spectrum twenty-four minutes more refrangible than Fraunhofer's line D. Many observations of the dark lines of the solar spectrum, compared with their positions in Kirchhoff's maps, having assured me that a minute of arc on this spectroscope corresponds between Fraunhofer's lines D and *b*, with 10·44 divisions of Kirchhoff's scale, the resulting difference of refrangibility between the green auroral line and Fraunhofer's line D is 250·6 divisions of Kirchhoff's scale; and its absolute position, assuming for that of D to be 1005 Kirchhoff, was within 10 or 20 units on either side of a place at about Kirchhoff 1255. A bright line in the spectrum of the aurora was observed by M. O. Struve at Pulkowa, in April 1868, whose position he ascertained to be within 10 or 15 units of the scale at Kirchhoff 1259, a place apparently identical with that of the bright line which was principally visible in last night's aurora. The faint and uncertain brightness of its appearance, while confining my attention principally to its observation, prevented me from searching in other parts of the spectrum for accompanying bright lines Within a space of about 400 Kirchhoff on each side of that which was recorded, I could, however, perceive no traces of any co-existing lines. The position of the bright lines which are most conspicuous in different auroras is, perhaps, a subject of interesting inquiry in connection with the yet unascertained laws which govern their appearance, and with the varying characters and peculiarities of their phases. A remarkable circumstance connected with the appearance of the single line observed on this occasion, was the flickering and frequent changes with which it rose and fell in brightness, apparently even more rapidly than the swiftly travelling waves, or pulsations of light, that repeatedly passed over the streamers, near the northern horizon, towards which the spectroscope was directed.

A. S. HERSCHEL

Andersonian University, Glasgow, April 10

THERE was a brilliant display of aurora borealis visible from this place on Sunday the 9th inst. I first noticed it about 10.45 P.M.; there was then a considerable luminosity in the N.W. with a magnificent red glow and streamers springing from the W. extending to within 20° of the eastern horizon, also radiation from other parts in the N. and N.W., but less brilliant. At about 10.55 P.M., a bright streamer made its appearance near the zenith crossing the red at right angles, and standing out clearly upon it. The aurora had nearly faded away at 11.10. When it was at its brightest through a direct-vision spectroscope with the slit rather wide and directed to the N.W., where there was scarcely any colour, the red and green bands usually seen under such circumstances were clearly defined, more particularly the red band. I then directed the spectroscope to the W., at a part where the red light was most intense, to my surprise the red band was scarcely to be discerned, and looked blurred, and spread out towards the green, which was better defined, but not clearly so. I several times repeated the observation with the same result. This, if confirmed by other observations, would appear to point to some fluorescent property of the upper atmosphere.

W. J. B. THOMPSON

Weybridge Heath, Surrey, April 11

THERE was a magnificent auroral display last night (Sunday), which commenced at 10.45 P.M., and continued till 11.15. The streamers radiated from a point due N.W., there being no clouds in their vicinity, the colour was a deep red, and they extended far beyond the zenith. At 11.20 another display was seen, but at right angles to the previous one, and streamed across the zenith due N. and S. When the sun had set there was an accumulation of stratified clouds near the western horizon and quite horizontal, these gradually rose radially, having their centre situated a little north of that of the aurora; and at about 11.10 the uppermost radii passed into the field of the northernmost streamers, so that it became impossible for me to distinguish between them which was cloud and which was auroral. After the first appearance had faded away, the second was seen to proceed from these clouds upon the latter passing overhead, but did not last longer than fifteen minutes, by which time the radial clouds had become so dissipated as to lose their character, and, to me, were almost invisible. I may mention that this peculiarity in the clouds was noticed on Saturday evening (the 8th inst.) after sunset.

The old superstition of bloodshed taking place in a distant country, and the red colour being the sign, is still prevalent; it was asked of me, by an observer, "whether there was a war in Paris, or was it on fire, as the reflection of something like it was in the sky?" Another declared he could hear "distant noises of the clashing of weapons." * But the assertion of an old woman who was amongst my interrogators, was that it was the reflection of fire, and "showed that *mahogany* was burning." The ignorance on this subject is appalling, and when we have such absurd accounts of the aurora borealis from persons of our own time, surely the obscure mentions of this phenomenon in the old chronicles (*vide* my article on this subject in NATURE for Dec. 29, 1870) by perhaps equally ignorant observers of nature, are not so difficult of interpretation as many imagine. The experience of the present is the key to the past.

JOHN JEREMIAH

43, Red Lion Street, Clerkenwell, April 10

ON Saturday, the 15th inst., a remarkably fine aurora was to be seen here towards the N.N.W. It was first observed at 8.45, and continued from then shining brightly till 9 P.M., when it made its disappearance. At first it formed a complete rose-coloured arch, in which flickering rays of bright white light were occasionally to be seen. During its appearance its position was gradually shifted round to the north, where it remained till it disappeared.

The Comparative Aggregate Strength of the Light from the Red Hydrogen-Stratum, and of that from the rest of the Chromosphere

I WAS a spectator of the total eclipse on December 22, and though I had no further connection with the Government expedition than that I was favoured with a passage home in H.M.S. *Urgent*, I was kindly permitted by the Rev. Mr. Perry and his party to set up my telescope at their observatory at San Antonio, near Port St. Mary, on the harbour of Cadiz.

I made an observation during the total phase, which I ought to have published sooner, but did not, partly from the distrust which an inexperienced observer naturally feels in his own results, and partly because I did not see that it might have some value. As I now think it may be of some interest, I will state what I saw.

The instrument which I used was one of Browning's direct-vision spectroscopes with seven prisms. It was not fitted to the telescope which I had with me, simply because I had not time to get them properly adapted to one another either before leaving England, or after arriving at Gibraltar by the Peninsular and Oriental steamer on December 16.

I spent the first thirty or forty seconds of totality in taking a general observation with the telescope; after that I gave it up to the friend who was travelling with me, and had fifty seconds at least during which I used the spectroscope. At first I tried to use it with the slit moderately narrow (about ·005in.); but, as there was much cloud over the moon, though not enough to prevent the corona and a slight amount of red light from the red hydrogen-stratum being seen with the naked eye, I could get no light to pass through the prisms while the slit was narrow; accordingly, I enlarged the slit to a width which would be absurd under most circumstances (about ·025in.), and then, taking a general view of the corona, saw a spectrum in which the red and green were present, but the blue and violet totally absent, and on this spectrum one line and one only: this line was strong compared with the rest of the spectrum, red, and of course broad to correspond with the width of the slit; and from its position on the continuous red part of the spectrum was either C or near it.

After I first saw this spectrum and line I had fully thirty seconds, which I employed in directing the slit as well as I could towards all parts of the corona, and in seeking for other lines; during the whole of the time I saw the same spectrum and the same red line only.

As this spectrum and line, from the nature of my instrument, must have proceeded from the mingled light of all parts of the chromosphere, I consider my observation as a humble imitation of that made by Mr. Pye, recorded in Prof. Young's article in NATURE for February 2 (p. 261). The mingled light was sufficient to give him with his delicate instrument the lines C, D, 1474; and he estimated the light of 1474 to be apparently greater than that of C, and to bear to it the ratio of 10 to 8·5; yet the light of 1474 was not sufficient to penetrate my rougher instrument, although the red line (which I can hardly doubt was C) showed conspicuously throughout the time that I turned the spectroscope upon the corona.

Whatever value my observation has it must be set in the balance against Mr. Pye's, and tends to weaken the argument by which Prof. Young attempts (in the article above-quoted) to show that the angular area of the self-luminous corona bears to that of the red hydrogen-stratum visible during totality so large a ratio as 35 or 70 to 1, and consequently extends 8′ or 16′ from the sun; in fact my observation tends to give a smaller extent of self-luminous corona than Mr. Pye's.

Mount Washington

TWICE recently it has been mentioned in your columns that Mount Washington in New England attains the height of 10,000 ft. If it were so its summit, for nearly 2,000 ft., would be clothed with perpetual snow. The most careful measurements—those of Prof. Guyot—give the height of the mountain as 6,288 ft.

SAMUEL H. SCUDDER

Mentone, April 13

[The communications in question were received from an American correspondent.—ED.]

The Name "Britain"

THE existence in former times of other Britains than those of our own island should not be overlooked in discussing the derivation of the word. According to Dr. Karl von Spruner's maps of France and Spain for the sixth century, besides the Britannia in the north-west of France, there was a town called Britonia (the present Mondonedo) in the north-west of Spain. Unless the similarity of these names is nothing more than a strange coincidence, it does not seem probable that the name Britannia can have any connection with the tin which is found only in one of the Britannias. Carte (vol. i. p. 10, note), speaking of the Phrygians (Briges) "the first nation that entered Europe," says, "of this sort are the people known over England, Scotland, and Ireland, by the name of Brigantes; the Britanni on the sea coast of Gallia Belgica; the Brigani mentioned by Pliny as seated in the Alpes . . . . . A Brigantium, now Braganza in Portugal; and another (town) of the same name, now Britanças

---

* How old and persistent this belief is may be shown by quoting a remarkable passage from Pliny. In Book II. chap. lvi., he says—"In the time of the Cimbrian Wars we have been told that armour was heard to rustle and the trumpet to sound out of heaven, and this happened very often both before and after those wars. But in the third consulship of Marius the Amerines and Tudertes saw men in arms in the sky, rushing one against another, from the east and west, and those from the west were discomfited. That the very firmament itself should be on fire is no wonder, for often it hath been seen when clouds have caught any great deal of fire." This same appearance is very probably that which Josephus refers to in his narrative of the terrors sent by God previous to the siege of Jerusalem.

or Corunna, called anciently Portus Brigantinus, in Gallicia." According to this the Briges would be the common ancestors of the Britons of England, France, and Spain, and the similarity of the names in these countries could be accounted for.

Faunas of Oceanic Islands

In NATURE, of February 16, I observe the reviewer of Mr. Godman's "Natural History of the Azores," makes the following statement:—"Mr. Godman appears to be the first who has, after a personal exploration of one of these oceanic groups, endeavoured to collect all that is known of its natural productions." Now, it is not with the intention of detracting from the merits of Mr. Godman's work, but merely to refresh the memory of your reviewer, that I beg to state, that I published in 1859 a small volume entitled "The Naturalist in Bermuda," which contained all that was known of the natural productions of those islands at that date. It was by no means a complete essay, but as stated in the preface "merely a prelude to a more complete publication on the same subject, which anticipated work, the result of several visits to the group, I hope to present to public notice shortly.

J. MATTHEW JONES

Institute of Natural Science, Halifax, Nova Scotia

Influence of Barometric Pressure on Ocean Currents

IN the recent discussions on the influence of barometric pressure upon ocean currents, I have not seen any allusion to the observations that have been made upon the effect of variations of barometric pressure upon the sea-level. In a memoir by M. Ch. Aimé, "Sur les variations de niveau de la Mediterranée," in the Annales de Chimie, tome xii., 1844, it is stated that a fall in the barometer is pretty uniformly accompanied by a rise in the sea-level to about thirteen times its amount. The Report of the British Association for 1841 contains a letter from my old friend, Mr. T. G. Bunt, of Bristol, stating that his observations upon the tide-gauge under his charge led him to conclude that a fall of one inch in the mercurial column was accompanied by an average rise of about 13½ inches in the high-water level. And the same industrious and careful observer, in a recent "Discussion of Tide Observations at Bristol" in the Philosophical Transactions for 1867, gives as the mean result of twenty-one years' examination of this point, "12·772 inches of tide to one inch of mercury." I referred to Mr. Bunt's observations in a discussion at the Geological Society (March 6, 1867) on a paper by the Earl of Selkirk "On some sea-water-level marks on the coast of Sweden," pointing out that some of the discrepancies in the observations as to the sea-level of the Baltic might be attributed without improbability to variations in barometric pressure. I have since learned from Admiral Key, who served in the Baltic fleet during the Russian war, that he had been led by his own observations to a like conclusion. And I find it stated in the description of the Baltic Sea, in the English Cyclopædia, that its level is sometimes observed to rise, and to remain thus elevated for a time without any obvious cause, two or three feet, of which phenomenon the explanation is probably the same.

I am sorry to find that I have not succeeded in convincing Mr. Laughton of the existence of a regular undercurrent in the Strait of Gibraltar. If he will take the trouble of carefully perusing the detailed report which I have presented to the Royal Society, he will find that he is quite in error in stating that I rest my affirmation upon "one observation after several attempts made in vain." All our observations, when rightly interpreted, tended to the same conclusion. The *reduction* of the boat's drift *almost to nothing*, in the first set of experiments, when it lay in a surface-current running nearly three miles an hour, with a breeze setting in the same direction, was just as conclusive evidence that a reverse current must have been acting on the current-drag below, as was the *reversal* of the boat's drift in the subsequent experiment, when the surface-current was less rapid and the opposing breeze diminished its action on the boat. And our observations of the Temperature and Specific Gravity of the 250 fathoms' stratum most unmistakeably indicated on both occasions its Mediterranean derivation.

I should like to know what is the precise minimum of movement which is held by Physical Geographers to constitute a *current*. There seems to me a great deal of confusion upon this point. The existence of an underflow of polar water towards the Equator cannot now be a matter of question. Commander Chimmo has recently obtained with the Miller-Casella thermometers a temperature of 33¼° at a depth of 2,306 fathoms nearly under the equator. What is the rate of this movement is a point as yet undetermined. But the rate of the northerly flow of warm surface-water between Scandinavia and Iceland, which is usually attributed to the Gulf Stream, but which I regard as the complement of the southward flow of deep polar water in a vertical oceanic circulation, is estimated by Admiral Irminger at from 1½ to 2½ miles per day. Is this, in the language of physical geography, a current?

WILLIAM B. CARPENTER

University of London, April 10

The "Times" Review of Darwin's "Descent of Man"

THE British public are deeply indebted to the *Times* Reviewer for his very comforting and reassuring remarks on Mr. Darwin's "Descent of Man," in which he has so well exposed the "utterly unsupported hypotheses," the "unsubstantial presumptions," the "cursory investigations," of that "reckless" and "unscientific" writer. It is a great satisfaction to find that Mr. Darwin's odious conclusion that the genealogy of the Talbots, and the Howards, and the Percys must be traced back beyond the Conqueror to an Anthropomorphous Ape, and beyond the ape to an Acephalous Mollusk, rests on no logical foundation whatever. The Reviewer well suggests that anything so odious in idea, so immoral in its apparent tendency, and so different from what we have been accustomed to believe, cannot possibly be true. One is so glad indeed to be free once and for ever from the mischievous influence of such "unpractical," "disintegrating speculations," that it seems worth while trying, if space can be found for the experiment, to elicit from the good nature of the Reviewer, or of those who think with him, a little clearer explanation here and there, before the subject is finally consigned to a well-merited oblivion.

Mr. Darwin is invited in one passage, "if he wishes to corroborate his hypothesis, to commence by experimenting on some superior kind of Ascidian, and see whether, by patient selection, he can induce any of them to split themselves in half, and abandon their permanent support for a vagrant oceanic existence." Now, it is a fact that among Corals or Polypes, which are not far removed from Ascidians, these interesting experiments are actually exhibited; for the cæspitose Corals, by what is called fissiparity, *do* split themselves in half, thus forming two complete individuals where only one grew before, and the Corals of the genus Fungia are fixed when very young, but subsequently break their pedicels and become free. The whole group of Zoophytes, recent and fossil, connects together marvellously different forms by an almost infinite series of wonderfully minute links. The study of such a group is therefore no doubt dangerous, if not decidedly pernicious, as tending to gloss over "the enormous and painful improbability" of Mr. Darwin's speculations. For if upon examination it seemed likely, or almost certain, that different genera of Polypes were connected with one another by descent, some rash enthusiast might think a similar conclusion not impossible in the order Primates. Fortunately, one is estopped from suggesting that in fact some genera of Polypes *may be* connected by descent, for fear of incurring the sharp reproach to which Mr. Darwin has so frequently laid himself open, of "conjugating the potential mood." Hitherto in most departments of thought and inquiry, probable evidence has been allowed to count for something, and most men are content to believe themselves to be the sons of their reputed fathers upon a mixture of evidence and authority, which, by the very nature of the case, can never rise to absolute demonstration. The Reviewer has done good service to society by showing the untrustworthy character of the foundation on which all our genealogies are built. It would be well in future if some auxiliary verb, expressive of doubt and uncertainty, could be combined with our patronymics.

Mr. Darwin, it appears, has "a facile method of observing superficial resemblances." For instance he surprises the apprehension of the vulgar by exhibiting the curious likeness between the embryos of a man and a dog. As every one of course knows how he looked when he was still in his mother's womb and less than an inch long, that stage in a man's career when he is only too like an embryo puppy, might have been shrouded under a delicate reserve. If, in place of this absurd "superficial resemblance," Mr. Darwin could have pointed out similarities between man and the lower animals in regard to minute structures of bone and muscle, or in the organs of sense or speech, his argument might have been deemed a little more scientific.

Persons who have read his book say that he does dwell with considerable force upon these very matters, but it is easy to see from the Reviewer's tone that they are mistaken, and that such investigations have been sacrificed to a glance or two at things on the surface. This is the more to be grieved and wondered at, because in his monograph on the Fossil Cirripedes and in his work on the Fertilisation of Orchids, Mr. Darwin showed an uncommon aptitude at "a thoroughly scientific *clairvoyance.*"

The Reviewer thinks it perfectly reasonable that the hand of a man and the foot of a horse, the flipper of a seal and the wing of a bat, should have all been formed upon the same general plan, without any connection by a common ancestry. It would be extremely gratifying to an inquiring mind, if he would explain upon this reasonable plan, the vast succession of creatures unveiled by geological research. Why have innumerable species been created and then destroyed? When did the creation begin, and when did it end? What causes, or if there were no causes properly so called, what caprice brought about the extinction of the mammoth, and led to the introduction of the modern species of elephant? Has the creative power been at last exhausted, or do sudden creations still occur, only in a shy sort of way, when no one is looking on? The Reviewer very sensibly censures Mr. Darwin and his followers for not specifying the year B.C. when the process of evolution first began. It is with the less diffidence, therefore, that a question is propounded above as to the date of the creation. The solution of this point of chronology will be awaited by many with extreme impatience, as different nations give very different accounts, and the Hebrews, who have a very ancient record, are by no means at one with themselves in the Hebrew and Greek editions of it. The number of years required for the process of evolution is confessedly indefinite, and as the whole hypothesis must, therefore, be destitute of any scientific value, it is no doubt quite fair on the Reviewer's part, to represent an indefinite number of years as equivalent to "infinite time." But the steps required for the process are also an indefinite number, and on this point he is less clear than elsewhere, for, referring to the old sophism respecting Achilles and the tortoise, he tells us, from Sir Isaac Newton, that "quantities ultimately coincide which may be proved to approach each other indefinitely, *within a finite time.*" From this it would seem that, if Darwinians could be content with the boundaries of geological time, the genealogies of men and apes might ultimately coincide. To avoid this miserable and preposterous conclusion, we are told that the solution of the sophism by Diogenes, "is the only true one," *solvitur ambulando.* We are further obligingly informed that this solution is *identical* with Newton's. And as Mr. Darwin cannot transform one species into another under our eyes, the eminently unpractical character of his speculations is triumphantly exhibited. It will be very impertinent if any one suggests that the instantaneous creation of a species has never yet been witnessed, and that those who believe in such occurrences ought, on the *solvitur ambulando* principle, to favour the world with, at least, one such exhibition. Captious persons may find fault with the Reviewer's opinion that the poetic faculty has received no development since Homer, and the religious sentiment none since the book of Genesis. They may call to mind that Moses and Socrates, and St. Paul and Luther, were guilty, like Mr. Darwin, of laying before popular audiences dangerous and "disintegrating" speculations; they may fancy that truth is worth discovering, even when it seems to involve some contradiction to our pride and some loss of comfort to our finer feelings, but such persons must be very captious, and the Reviewer will, doubtless, know how to deal with them.

Torquay, April 15 THOMAS R. R. STEBBING

Sexual Selection

IN the first volume of "The Descent of Man," at page 396, Mr. Darwin says, referring to butterflies, that "the lower surface (of the wings) generally affords to entomologists the most useful character for detecting the affinities of the various species." I think, also, that this lower surface might afford another link in the chain of argument by which Mr. Darwin supports his theory of Sexual Selection. Thus, for example, to speak of British species only, in the cabbage butterflies, the under surface of the wings is alike in both sexes of *Pieris Brassicæ.* The black spots, however, which appear on both surfaces of the fore wing of the female vanish from the upper surface of that of the male, probably because the female has some dislike to them. There is no difference in food-plant, habit, or need of protection here; the only explanation seems to be a whim of the female or a whim of nature, and we have lately discarded all thought of nature being freakish. In *P. Rapæ* and *P. Napi* a similar difference prevails, though less constant and in a degree less marked. In the allied *Anthocharis Cardamines* the under surface of both sexes is alike, notwithstanding the vast difference of their upper surfaces. When these butterflies alight and close their wings, the under surfaces of the *hind wings* are alone visible, and these are, apparently, the parts of the insect modified for the sake of protection. The simple yellow in *Brassicæ* and *Rapæ*, the green-veined yellow in *Napi*, the green marbling in *Cardamines*, of the under sides of the hind wings, are well fitted to conceal those insects as they settle on the wild flowers which they prefer.

Again in *Hipparchia Janira* the light brown patch so conspicuous on the upper surface of the fore wing of the female vanishes from that of the male; and in *H. Tithonus* and *H. hyperanthus* a tendency to decrease the quantity of light colour on the upper surface of the male butterfly prevails. So is it also with one of the Hair Streaks, *Thecla Betulæ*, the under surface still remaining alike in both sexes of these different species. In this case the female butterflies would seem to wish their partners to be of a duskier hue than it is granted to themselves to be. The differences mentioned above are so slight that Mr. Darwin says at page 317, "With those (butterflies) which are plain-coloured, as the meadow-browns (*Hipparchiæ*) the sexes are alike." But it will be admitted that though these differences *are* slight they are yet important, as showing a tendency, more or less marked, to follow the rule which Mr. Darwin has laid down; and every sign of such a tendency strengthens his case.

In *Apatura Iris* the under surface of both sexes is alike, though the male has his upper surface glorified with purple for the delight of his plain brown wife. In the blues, *Polyommatus Alexis*, *P. Corydon*, *P. Adonis*, and *P. Ægon*, the under surface of both sexes is also alike, though in the males the blue and in the females the brown of the upper surface forms the background of the spotty design. The blue blood is very strong in these butterflies, and will show itself sometimes even in the females; who, if powerless over their own decoration, have at least succeeded in bringing out the innate splendour of their handsome husbands. With the blues, as with the cabbage butterflies, the under surface of the hind-wings seems specially adapted for protective purposes; every butterfly-hunter knows how difficult it is to distinguish the common blue when it is sitting, shut up, on a scabious flower. It is the same with the small copper butterfly, which has its under surface dotted very similarly. But burnished copper and dazzling blue are not colours for protection, surely. We may give the under surface to Mr. Wallace, but we must yield the upper surface to Mr. Darwin.

At page 399, speaking of the ghost moth (*Hepialus humuli*) and others of the moth kind, Mr. Darwin says, "It is difficult to conjecture what the meaning can be of these differences between the sexes of darkness or lightness; but we can hardly suppose that they are the results of mere variability, with sexually-limited inheritance, independently of any benefit thus derived." The female ghost moth follows Mr. Darwin's rule, that females are most conservative of the features of kinship. In her colouring she closely resembles the other *Hepialidæ*. And the male, notwithstanding his shining shroud, keeps to the same sober under-colouring as his mate. Now *H. humuli* is more nocturnal in its habits than any of the other species in the genus *Hepialus;* I have caught *H. hectus* and *H. lupulinus* flying in bright sunshine, but I have never seen the ghost moth until dusk was far advanced. May it not be that sexual selection has come into play here by the female preferring the *whitest* male, he being the most distinguished when all colour has faded into dimness? She could not decide between differing patterns of gold and amber at that hour, but a snow-white surface would then be quite visible. The fact mentioned at page 402, that "in the Shetland Islands males (of *H. humuli*) are frequently found which closely resemble the females" (I have seen similarly varied males in Peterhead collections), would seem to confirm this theory; for the twilight of the north, at the season when the ghost-moth abounds, is so bereft of dusk that whiteness would not be needed to render the males visible.

It is possible that those acquainted with the habits of the other moths, of which Mr. Darwin speaks, may be able to reconcile their appearance with the rules of Sexual Selection which he has laid down so clearly and illustrated so fully in his last great work. GEORGE FRASER

169, Camden Road, London, N.W.

SCIENCE IN PARIS DURING THE SIEGE

IN a somewhat striking passage in the *De Augmentis Scientiarum* Francis Bacon contrasts the endurance of monuments of learning with that of those raised by the hand of man. The verses of Homer, he reminds us, have endured for more than twenty centuries, during which time numberless palaces, temples, and cities have disappeared from the face of the earth. Some such reflection as this may have induced the members of the *Académie des Sciences* of Paris to continue their weekly meetings with perfect regularity during the bombardment. While everything else was turned upside down, while a dynasty was passing away, while sons and brothers were perishing around them, an enemy at their gates, want within their walls, and missiles of war threatening themselves and their household gods, these men continued their usual studies. We are reminded of Archimedes at the siege of Syracuse, save that there we have but one man, while here it is a large body of the intellectual flower of the country. Some of the more active of the members are men who have attained that philosophic calm, which not even the terrors of war can dispel, nothing diverts them from the even tenour of their way—

Si fractus illabatur orbis,
Impavidum ferient ruinæ.

We frequently meet with the names of Dumas, Elie de Beaumont, and Chevreul in the *Comptes Rendus* published during the siege. The youngest of these men was born in the last year of the last century; they have seen every phase of Parisian life, are men of infinite experience and learning, the very soul of the Academy; they have held office under various Governments, have seen more than one revolution; barricades and street fighting, and the Parthian cap are no novelty to them; but with all their experience they had never beheld a bombardment of Paris; yet, all honour to them, they did not abate one jot of their Academic work. Perhaps the members may have felt it a relief to have to deal with immutable and indestructible facts, while everything around them was so mutable and perishing. Perhaps they remembered a saying of one of their countrymen:—" L'homme n'a pas de self-critérium. L'indestructibilité du fait est le critérium unique, infaillible, absolu, multiple, un, présent dans tous les ordres des connaissances."*

The papers read before the Academy during the period of the siege relate for the most part to matters connected with war and to the food resources of a besieged city. M. Payen writes on hippophagy, M. Frémy on the use of osseine as food, M. Riche on the use of black puddings of ox-blood. In the *Revue des Cours Scientifiques* we also find some important papers by M. Bouchardat on the food supply of Paris, and a paper by the same author on the sanitary condition of the city during the siege, and during the same months of the preceding year. M. Berthelot has contributed some important papers on the force of various explosive substances, both solid, liquid, and gaseous. These papers are well worthy the attention of our war authorities. There is also a paper on dynamite, by M. Champion, and on the ignition of gunpowder at a distance by means of electricity. The subject of balloons and ballooning, of course, engages a good deal of discussion. M. Marey contributes several important papers on the motions of birds during flight, accompanied by graphic representations of them, registered somewhat after the manner of the vibrations of a tuning fork, and shown by sinuous lines. The diagram representing the vertical oscillations of a wild duck during flight is very striking. Beyond these papers there is nothing of much importance.

Here, for example, are the principal papers of one number (December 5th) taken at random:—

* *Philosophie Méthodique*, par J. de Strada, a work too little known in this country.

M. Milne-Edwards discusses the nutritive value of organic substances contained in bones, and the proper rations for sustaining the human body in a perfect state of health; M. Chevreul makes observations upon M. Frémy's paper on the use of osseine as food; M. Gazeau details various experiments on the nutritive properties of cocoa leaves; M. Montier treats of the specific heat of gases under constant volume; M. Riche of the preparation of osseine and gelatine; and M. Castelhaz of the refining of crude tallow.

The future historian of science will wonder when he reads in the *Comptes Rendus* for January 9, 1871:—

M. Chevreul donne lecture à l'Académie de la déclaration suivante :

"Le jardin des plantes médicinales, fondé à Paris par édit du Roi Louis XIII. la date du mois de janvier, 1626.

"Devenu le Muséum d'Histoire naturelle par décret de la Convention du 10 de juin 1793.

"Fut bombardé,

"Sous le règne de Guillaume I^er roi de Prusse, Comte de Bismark chancelier,

"Par l'armée Prussienne, dans la nuit du 8 au 9 de janvier, 1871.

"Jusque-là, il avait été respecté de tous les partis et de tous les pouvoirs nationaux et étrangers.

"E. CHEVREUL, *Directeur*."

He will grieve when he reads " M. Le Président annonce à l'Académie la douloureuse nouvelle, malheureusement très-probable, de la mort du . . . ." occurring too often in what should be only a record of the living and of their work. So we grieve: and yet more when we see the intellectual resources and energies of a great country paralysed, and the whole current of its active thought diverted no man knows whither; while its schools and colleges are empty, and many of those who should be in them have been killed untimely to satisfy the necessities of war. G. F. RODWELL

AMERICAN NOTES

WE learn from *Harper's Weekly* that the fourth volume of the " Report of the Geological Survey of Illinois," which has been in progress for several years past, under the direction of Prof. A. H. Worthen, has just been published. Like its predecessors, it is a handsome book, well illustrated, and containing much important matter relating to the geology and physical features of the State. This volume is occupied by a detailed account from assistants in the survey in regard to particular counties in the State, followed by systematic papers—one upon the fossil fishes by Prof. J. S. Newberry and Prof. Worthen, and the other upon fossil plants by Prof. Lesquereaux, illustrated by a number of well engraved steel plates. The economical value of such a survey to the State, conducted with the spirit and efficiency which have marked Prof. Worthen's administration from the beginning, is exceedingly great, and cannot be estimated in dollars and cents. Not merely does it furnish a fund of information to the residents of Illinois, but it supplies an official guarantee to others in regard to the resources of the State which could not be obtained in any other way.—We have, in a previous article, referred to some interesting speculations by Prof. Shaler, of Cambridge, upon the formation of the New England coast; and we find in the proceedings of the Boston Society of Natural History for February last some additional remarks by him on the same subject. He considers that the Chesapeake and Delaware bays, like many of the deep gorges in Switzerland and elsewhere, were formed by the action of ice, and that the existence of Cape Hatteras is due to the uplifting of the rocks on which Richmond is situated. The sand-bars on the coast he believes to have been formed by the material dug out of the Delaware and Chesapeake bays by this ice action, and worked southward by the united force of the floods and currents. He finds that, after we pass these bars, south of Weldon, the sea-bottom is totally distinct in character, being purely submarine, and formed by the action of the sea. He points out the existence of a rise and fall of the coast at different portions of its extent; this, in the most recent geological period, amounting at Charleston, South Carolina, to from 50 to 60 feet, in Maine to 200 feet, and to a still greater extent on the coast of Labrador. As a general rule, he thought there was evidence to prove that, taking a line from the centre of the continent to the centre of the sea, the sea-floor was coming up and the high elevations were coming down.—Mr. Hyatt states that observations made by the Coast Survey showed that the coast of Long Island Sound, and southward to New Jersey, has been sinking, while the Florida Keys are rising; and Mr. Niles remarked that, from the earliest times, in the Adirondacks and different points southerly, there had been peninsulas corresponding in position to Florida, and that this is simply the most southern and latest of a succession from north to south.—At a meeting of the New York Lyceum of Natural History, held during last autumn, Prof. Newberry, the President, exhibited the anterior portion of the cranium of a walrus which had been found during the summer at Long Branch by a gentleman whose foot struck against it while bathing. It was strongly silicified, but exhibited no appreciable difference from modern specimens. The precise age of this fossil could not, of course, be ascertained, although it is well known that its range was formerly much south of its present habitat. It is not unfrequently brought down on floating ice off the coast of Newfoundland; and although Labrador is at present the southern limit of its residence, it was once very abundant in the Gulf of St. Lawrence, and its remains have been found in the shell heaps of the Bay of Fundy. It is probable that the specimen exhibited by Prof. Newberry is a relic of the glacial period, although it was suggested that it might have been of the tertiary age, which probably cannot be verified. Other specimens of similar character are recorded as having been found on Martha's Vineyard; in Monmouth Co., New Jersey; and in Accomac Co., Virginia.—We have already referred to the detection of an ancient bone cave near Phœnixville, Pennsylvania, and about twenty-five miles north-west of Philadelphia, and to the interest which has attached to this discovery. Since our last account Prof. Cope has been actively engaged in the investigation of the collection, and already reports the existence of about thirty species of vertebrates, together with numerous plants and insects. All of these, so far as known, are probably of extinct species, although their precise relationships have not yet been fully worked out. Among the reptiles were tortoises and serpents, and of birds there was a turkey and a snipe. The mammals, as Prof. Cope anticipated, were most numerous, these including two carnivorous animals of large size, one of them a cat, and the other a bear, previously described by Dr. Leidy, of a remarkable type, and totally distinct from the cave bear, or any living species of either Europe or America. At least three species of sloths were discovered, mostly of gigantic size, one of them a species of *Megalonyx*, and two of *Mylodon*. Besides these, there were some ruminating animals, tapirs, and a small horse. With the other remains were the teeth and tusks of the mastodon. The fissure in which the bones were found was forty feet deep and fifteen feet wide; the length as yet has not been determined. Above the deposit of bones the cave was filled with washings of the Triassic age from the neighbouring hills.

SCIENCE AT OXFORD

THE following courses of lectures in Science are announced for the ensuing term:—The Regius Professor of Medicine (Dr. Acland) will continue his clinical instruction at the Infirmary, on Tuesdays and Saturdays, beginning on Tuesday, May 2, at 11 A.M. The Linacre Professor of Anatomy and Physiology (Dr. Rolleston) proposes to form classes for practical instruction in anatomy and physiology, as in former terms. Persons are invited to come to the anatomical department in the New Museum on two mornings of the week for study and demonstration, and to lectures on Saturdays at 1 P.M., and at such other times as may be hereafter arranged. The Sedleian Professor of Natural Philosophy (the Rev. Bartholomew Price) will give a course of lectures on the Solution of Problems in Applied Mathematics. The course will begin at 1 P.M. on Thursday, April 20, in the lecture-room, upper corridor south, Museum. The Savilian Professor of Astronomy (the Rev. C. Pritchard) will give a lecture early in the present term on the recent solar eclipse. He will also be ready to assist members of the University in their astronomical studies, "*sine ullâ solennitate.*" The Savilian Professor of Geometry (Mr. Henry Smith) will continue his lectures on the Anharmonic Properties of Figures. He will also give a course of lectures on Geometry of Three Dimensions. The Professor of Geology (Mr. J. Phillips) will begin a course of lectures on Monday, April 24, at 12 o'clock, and continue them at the same hour on succeeding Wednesdays and Mondays, in the New Museum. The lectures are arranged to present a systematic view of the more remarkable groups of organic remains, especially in the extinct groups. The Professor of Experimental Philosophy (Mr. R. B. Clifton) has given notice that the Physical Laboratory of the University will be open daily for instruction in practical physics, from 10 A.M. to 4 P.M., on and after Wednesday, April 19. The fee for working three days a week during the term is 3*l*. The Professor of Chemistry (Sir B. Brodie) has given notice that the Demonstrator in Chemistry will deliver a course of lectures on Chemistry on Tuesdays and Saturdays, at 11 A.M., commencing Tuesday, April 25. These lectures will be in continuation of the course of the Professor of Chemistry last term, and will commence with the element phosphorus and its combinations. The Professor of Botany (Mr. Lawson) will give a course of lectures on Structural and Physiological Botany. The Hope Professor of Zoology (Mr. Westwood) proposes to give a short course of lectures on the Articulated Animals.

SETTLE CAVE EXPLORATION

AT the last meeting of the Settle Cave Exploration Committee, the report of the excavation of the Victoria Cave, up to December 31st, 1870, by Mr. Boyd Dawkins, was read.

The results of the exploration are full of interest, and bid fair to throw light on the social condition of the Romano-Celtic inhabitants of Ribblesdale after the withdrawal of the Roman legions. The committee placed the superintendence of their exploration in the charge of Mr. Jackson, the discoverer of the cave, and began work with the kind permission of the owner (Mr. Stackhouse), by clearing away a mass of debris, which very nearly blocked up the lower entrance and formed a horizontal plateau extending some thirty feet from the solid rock. On the surface there was a stratum of angular stones which had fallen from the weathered face of the rock above, and passed into the cave at the bottom of the Attermire ravine. Below was the layer which furnished traces of man. Mixed with charcoal there were large quantities of the bones and teeth of the Celtic short-horn (*Bos longifrons*), goat, and horse, and a few remains of red deer and roe deer, which were evidently the refuse of human food. There were also fragments of pottery, bone pins, and various nondescript articles in antler and bone, stone pot-boilers, and two perforated discs of stone which had been used as spindle-whorls. As this layer passed into the cave, it rose to the surface and continued to furnish the same class of remains as those found outside. The personal ornaments are the most worthy of note. Besides bronze harp-shaped brooches of the common late Roman type, there were two in gilt-bronze, of a sigmoid shape, and adorned with a singularly beautiful pattern in blue, yellow, red, and green enamel. They are undoubtedly of a style purely Celtic. A harp-shaped brooch, Roman in design, is adorned with a most delicate pattern in blue and red enamel. Among the other brooches, one small oblong enamel is of a form hitherto unknown in brooches of this date, while a second consists of a small disc of bronze, with a plate soldered to it bearing a flamboyant ornament of Celtic design. There were also bronze gilt armlets. The whole evidence furnished by the personal ornaments in a word points to their Romano-Celtic origin, and it is not improbable that the principal seat of the art of enamelling was Yorkshire, the few enamels of that particular kind which have been found occurring, with one or two exceptions, in that county. The date of the occupation is shown by the coins, which range from Trajan down to the barbarous imitations of the coins of Tetricus. The latter were in circulation in the fourth and fifth centuries, and probably continued to be used in that portion of the Romano-Celtic kingdom of Strathclyde down to its final conquest by Eadberht in 756 A.D. The whole group of remains is precisely of the same character as those found around the ruins of Roman villas in Britain, and has probably been introduced by Romano-Celtic inhabitants who fled from their luxurious homes to take refuge from the ravages of the Picts or Scots, or of the Northumbrian Angles, who were pressing on that portion of the frontier of Strathclyde during the 5th, 6th, and 7th centuries. To suppose that people using articles of luxury such as those found in the cave would have chosen such an inclement abode, except under the pressure of necessity, is unreasonable.

At the entrance below the Romano-Celtic strata a layer of angular debris fallen from the cliff above, six feet thick, rested on a thick deposit of gray clay. At their point of junction a curious bone harpoon, a bone bead, the remains of red deer, horse and Celtic short-horn, and of bear, were found, which testified to the occupation of the cave by man long before the Romano-Celts used it as a refuge. The two flint flakes and two lumps of red ruddle found were probably obtained from this lower horizon, which, as the talus died away at the entrance of the cave, became confused inside with the Romano-Celtic stratum immediately above. It is probably of Neolithic age.

The grey clay underneath was homogeneous and very tenacious, and as the layer dipped away from the entrance, it must have been introduced by water flowing from the ravine into the cave. It was resolved to give up the attempt to fathom this bed of clay, after sinking a shaft twenty-five feet deep without any results.

The committee are desirous of exploring others of the many caves in the neighbourhood, if they can obtain support necessary to carry on a work which is of almost equal interest to the archæologist and to the historian.

NEW SPECIES OF MADREPORE

MR. W. SAVILLE KENT read a paper at a recent meeting of the Zoological Society on various new species of Madrepores, or Stony Corals, met with by himself while engaged upon arranging, naming, and cataloguing the fine series contained in the British Museum. Among the more interesting of these, commencing with the family of Turbinolidæ, Mr. Kent drew attention to a fine species of *Acanthocyathus* from Japan, more closely allied to a Maltese Miocene form (*A. Hastingsæ*) than to any known existing one; and also to a *Flabellum* allied to *F. Anthophyllites*, whose most remarkable feature rests in the phenomena connected with its reproduction by the process of gemmation, which invariably results in the destruction of the parent; the reproductive bud always originating within the margin of the parent calyx, which, in the course of its development, it splits to pieces. For this aberrant form Mr. Kent proposes the appropriate name of *Flabellum matricidum*. In the family of the Oculinidæ, which comprises the majority of the species introduced by Mr. Kent, are three new forms of *Allopora*, and numerous ones of *Stylaster*, *Distichopora* and *Amphihelia*, the first-named genus in particular containing a magnificent arborescent species, upwards of a foot in height, of a delicate rose colour, having a stem of such thickness and of such dense consistence that Mr. Kent is of the opinion that, if procurable in any quantity, it may eventually prove of high economic value, and even replace to some extent the well-known *Corallium rubrum*. The examination of these new varieties has enabled Mr. Kent to define more precisely the characters of *Allopora*, and its true distinctions from *Stylaster*, *Distichopora*, and other allied genera. In all, Mr. Kent introduces some twenty species as new to science.

SUBTERRANEAN ELECTRICAL DISTURBANCES

A FEW minutes before and after the earthquakes of the 17th March last powerful positive electrical currents were rushing towards England through the two Anglo-American telegraph cables, which are broken near Trinity Bay, Newfoundland. Mr. C. F. Varley, C.E., who informed us of the fact, broaches the novel speculation that some earthquakes may be due to subterranean lightning. He imagines that as the hot centre of the earth is approached, a layer of hot dried rock may be found which is an insulator, while the red hot mass lower down is a conductor. If this conjecture be true—and there is plausibility in it—then the world itself is an enormous Leyden jar, which only requires charging to a very moderate degree to be equal to the production of terrific explosive discharges.

The French Atlantic cable was disturbed at the same time, and so were many of the English land-lines, but the only observations as to the direction of the current were made by means of the Anglo-American telegraph cables.

A number of Mr. Varley's charts about earth-currents were published in the Government Blue Book of 1859-60, showing that the direction of these currents across England was in a very notable degree determined by the contour of the coast, and that the same auroral discharges would often produce currents at right angles to each other in direction, in different parts of Britain.

NOTES

A PROPOSAL has been made that certain Medical Schools on the north and south sides of the river should be amalgamated, in order that, by concentration of power, the teaching shall be made more efficient than it is at present, the teachers being able to devote themselves more unreservedly to their duties than they possibly can do under existing arrangements. The absolute necessity of some such arrangement as this is obvious.

MR. RUTHERFORD and M. Janssen, to whose labours cosmical physics owes so much, are both now in this country, the former, we regret to learn, in consequence of a peremptory order to cease work for a time. At the last meeting of the Royal Astronomical Society, Mr. Rutherford exhibited his exquisite photograph of the Pleiades, which represents the last important outcome of celestial photography. It appears that M. Janssen's observatory for solar research, which had been erected in one of the pavilions of the Palace of St. Cloud, at the cost of the Emperor, was one of the first buildings to be entirely destroyed by the German fire.

THE Royal Commission on Scientific Instruction and the Advancement of Science will resume its sittings on the 25th instant.

THE Marine Aquarium at the Crystal Palace is beginning to take form, thanks to the energy of Mr. Lloyd. About one-third of the 700 tons (= 150,000 gallons) of the sea water required is already in the tanks, but the steam engines and pumps are not yet regularly at work. When they are, and some of the marine animals of which at present the aquarium is quite destitute shall have been received, we hope to give a description of an enterprise of which great scientific use can certainly be made.

WE learn from the *Chemical News* that the Council of the Federal Swiss Polytechnic School at Zürich has appointed Dr. Emile Kopp as Professor of Technology in the room of the late lamented Dr. Bolley. Professor Kopp's merits, during the time he has held the Professorship at the Institute Superiore, at Turin, have been gracefully acknowledged by the Italian Government, it having pleased H.M. King Victor Emmanuel to grant to Dr. Kopp the dignity of Commandeur de l'Ordre Equestre de la Couronne d'Italie. We sincerely congratulate Dr. Kopp, and no less so the Government of the Helvetian Republic, on having secured the services of a man so eminently well suited as Dr. Kopp to the important Professorship vacant by the demise of Dr. Bolley.

THE French Academy of Sciences held a short sitting on April 3, M. Faye, who usually occupies the chair, being, however, absent. The principal subject of interest was a sharp passage of arms between M. Delaunay and M. St. Claire Deville respecting the Montsouris Observatory. The Commune having ordered the arrest of M. Henri St. Claire Deville, the Professor of Chemistry in the University, as a hostage, he has been compelled to make his escape to Versailles, together with his brother, the meteorologist. M. Leverrier is also now at Versailles. Dr. Bersigny, who conducted the observations during the Prussian occupation, will be the director of the meteorological observations conducted by the Government.

THE second *soirée* of the Royal Society takes place on Saturday evening next, and that of the Linnean Society on Wednesday the 26th inst.

WE understand that there is likely to be a contest for the seat in the Senate of the University of London, vacant by the death of Prof. Miller. The nomination would, in accordance with previous practice, be left this time to the Faculties of Science and Medicine, and their representative is Dr. Parkes, F.R.S., of Netley, who is also supported by many graduates in Arts.

THE course of lectures during the Easter term at the Gresham College, by Dr. E. Symes Thompson, Gresham Professor of Medicine, will be on April 21, 22, and 24, the subjects being, "On the Small-pox Epidemic," "On the Organs of Respiration," and "On the Organs of Circulation." These will be followed by two lectures on May 24 and 25, "On the Water-supply of London," and "On the Heart and Lungs in Health and Disease. As usual the lectures are free to the public.

IT is rumoured that a College for Women is to be established at Cambridge, in order to give the students the advantage of attending the lectures, &c., of the University Professors.

THE following are places of Comet I., 1871, discovered by Dr. Winnecke, for the dates named:—1871, April 7, $9^h\ 50^m\ 31^s$, M. T. Karlsruhe; AR app. ☌ = $2^h\ 27^m\ 14^s{\cdot}59$ Decl. app. ☌ = $+\ 53°\ 53'\ 8''{\cdot}1$. April 8, $9^h\ 39^m\ 43^s$, M. T. Altona; AR app. = $2^h\ 32^m\ 8^s{\cdot}21$; Decl. app. = $+53°\ 24'\ 41''{\cdot}1$. April 9, $9^h\ 56^m\ 25^s$, M. T. Altona; AR app. = $2^h\ 37^m\ 2^s{\cdot}50$ Decl. app. = $+52°,\ 55'\ 31''{\cdot}0$.

IN a recent number of Poggendorff's *Annalen*, Dr. Weinhold states that the black absorption line of sodium can be easily obtained by a simple process. The usual method has been to interpose a flame, coloured with chloride of sodium, between a strong light, such as the electric light, and the slit of a spectroscope. The source of light now proposed by M. Weinhold is an ordinary petroleum lamp; the light is allowed to pass through a slit directly on to a prism, and a spirit lamp flame, intensely coloured with chloride of sodium, interposed between the prism and the eye, so as to cover the entire spectrum;—the black absorption line will then be seen distinctly. If the flame coloured with sodium is placed in front of the slit, the bright yellow line will be seen as usual. M. Weinhold has not been successful in using this method with an ordinary spectroscope fitted with telescopes, on account of various practical difficulties.

M. GABRIEL MORTELLET, the sub-conservator of the St. Germain Museum, wishes us to correct a statement which seemed to imply that it was open during the Prussian siege. This was not the case, although the works were not interrupted.

THE temperature of February and March shows a remarkable contrast to that of the two preceding months. Mr. Glaisher's tables, published in the *Gardener's Chronicle*, show that at Blackheath on forty-seven days during these two months the temperature was above the average, while it was below the average on only twelve days, the mean being $3°{\cdot}55$ above that of the same period during the last fifty years. The disturbance of equilibrium caused by the low temperature of December and January has thus almost been restored. During Feburary the thermometer only fell to the freezing-point on five nights, and during March east winds prevailed to only a very moderate extent, showing a very marked contrast to the same month last year. The depression of temperature which commenced on March 28 continued to April 11, when there was a sudden rise from $4°{\cdot}1$ below the average to $11°{\cdot}4$ above the mean on April 12.

THE publication is announced of a new series of the "Messenger of Mathematics." It will be edited by Messrs. W. Allen Whitworth, C. Taylor, W. J. Lewis, R. Pendlebury, and J. W. L. Glaisher, and the first number will be published by Messrs. Macmillan on May 1st. The editors consider that the "Messenger" has, during the five years it has already existed, amply fulfilled its object of encouraging original research in the three Universities among junior graduates and others, although no inconsiderable portion of its contents has been supplied by writers of established reputation, who rank amongst the foremost mathematicians of the age; and it is this fact in particular which now induces them to appeal directly to the mathematical world at large, and to remove from their title-page any words which might be supposed to limit the sphere of usefulness of the "Messenger." They are therefore prepared to receive communications from every available source, and have already to announce papers, forwarded or promised, by Prof. Cayley, Chief Justice Cockle, Mr. Routh, Mr. Esson, and others. Besides original papers, it is intended to insert brief notices of select articles or treatises on mathematical subjects, as well as short accounts of the proceedings of societies at home or abroad.

THE second series of "Science Lectures for the People," delivered in the Hulme Town Hall, the first of which we have already had occasion to notice in terms of commendation, contains reports of lectures by Professor W. C. Williamson on "The Natural History of Paving-Stones," Dr. W. B. Carpenter on "The Temperature and Animal Life of the Deep Sea,' Mr. A. H. Green "More about Coal," and Mr. Norman Lockyer "On the Sun." It is published by Mr. John Heywood, Deansgate, Manchester, and Messrs. Simpkin, Marshall and Co., London.

THE second part of the fifth volume of the "Proceedings of the Bristol Naturalists' Society," from May to December 1870, does not contain much original matter. The longest paper, by Messrs. Sorby and Butler, "On the Structure of Rubies, Sapphires, Diamonds, and other Minerals," has already appeared in the "Proceedings of the Royal Society." The paper "On the Natural History of Filey and its Neighbourhood," however excellent in itself, hardly appears to us in place among the proceedings of a local society on the other side of England. Mr. C. F. Ravis contributes a useful paper, "On Denudation, especially as exhibited in the Valley of the Avon," and there are some good local geological and entomological notes. The zoological and botanical sections present no report.

COLONEL HAIG, R.E., of the Godavery Navigation Works, has found coal near Dumagudlom, in the Madras Presidency, 130 miles from Kokonada. It is not so good as English coal for locomotive purposes, but is good enough for welding in the Government workshops.

MR. MALLET, of the Indian Geological Survey, has been examining Aden with a view to water supply. He considers there is no hope from Artesian wells, but recommends water to be brought from wells near Mahilla at the Sheikh Othman aqueduct.

THE culture of bamboo for paper making and other purposes is being promoted by the Government of Central India. The Indian Government is buying land in the hill district of the Neilgheries for a spice plantation. Col. Boddam has proposed the cultivation of the sunflower in Mysore. It is very successful in France. Government has sent out six more Scotch gardeners for experimental cotton growing. These men have answered very well.

THE Broom (*Sarothamnus scoparius*) is extremely abundant in Madeira, but is supposed to have been originally introduced to the island. It is now sown extensively on the mountains for the purpose of being cut down for firing, or burnt on the spot every five to seven years to fertilise the ground. The twigs and more slender branches are also used commonly as withs for binding bundles of faggots, brushwood, fern, &c.; and numbers of country people, especially young girls and children, residing within reach of Funchal, gain a livelihood by bringing daily into the town bundles of broom for use in heating ovens, &c. The fine and delicate basket-work peculiar to Madeira is manufactured from the slender peeled twigs of this plant. Mr. Lowe speaks of a variety with pure white flowers which occurs on this island.

THE Apocynaceæ are noted for their poisonous properties, and one of the most interesting plants of the order is *Cerbera odollam*. It is a tree about 20ft. high, growing about Malabar, and Travancore, and produces a drupe-like fruit as large as a fine mango. The inner shell of the fruit, after removing the green rind, is composed of a mass of reticulated woody fibres, and when dry is not much unlike a ball of coarse, dirty string. These fruits are said to be used by the natives in Travancore to poison dogs, for this purpose they are taken when green and covered with sugar or some sweet substance, by which the dogs are tempted to eat them. The effect of the poison is to cause the teeth of the animals to become loose or to fall out before death ensues.

A NEW kind of stuffing for mattresses appears to be coming in vogue, for we learn from the *Journal of Applied Chemistry*, "that sponge, dipped in glycerine and well pressed, remains elastic, and can be used for mattresses, cushions, and general upholstery," and we further learn that "sponge mattresses prepared in this way, are now finding great favour."

THE *Pharmaceutical Journal* draws attention to an article which originally appeared in the *American Journal of Microscopy*, on the value of the microscope to the pharmacist in the detection of parasitic animalculæ or fungi in drugs of vegetable origin. We all know that leaves, roots, and seeds deteriorate very much by being kept any length of time, therefore the remarks of the author are of the utmost importance to mankind generally. He says "that it is notorious that the most carefully prepared tinctures and extracts of certain drugs are sometimes devoid of medicinal power. It has been supposed that certain volatile constituents escape from the substances from which such tinctures are prepared, but of this we have no certain proof. Why is it that the leaves of belladonna may, in some instances, be kept for years, and at the end of that period be capable of yielding a reliable preparation, while other specimens, when kept only a few months, are worthless? It must be because of some destructive process going on in the substance, which cannot be discovered with the naked eye." The hints which follow are even worth the attention of those upon whom we depend for our medicinal preparations. "The pharmacist should first learn to recognise the natural healthy appearance, under the microscope, of all the vegetable substances he works upon; then he should subject a specimen of every substance he prepares to a careful examination, and if he discovers the presence of vegetable or animal parasites, such substances should be rejected. The world is flooded with inert medicinal preparations. Doubtless many such preparations are made worthless by improper methods of manufacture; but it is my opinion that in many instances their worthlessness is due to the fact that the substances used have been injured by certain agencies which could have been discovered by the intelligent use of the microscope."

THE *Eucalypti*, or Gum-trees of Australia, are well-known for their hard wood as well as for the oils and gums yielded by many of them. Some of the species have been introduced and successfully grown in different parts of Europe, and their products may become, ere long, recognised articles of import. At the present time large quantities of sticks of a species of *Eucalyptus* are imported into England from Algeria, and are made into walking sticks. During the Great Exhibition in Paris in 1867, the leaves of *Eucalyptus globulus* were made into cigars, and recommended as being very efficient in aiding digestion. We now learn from the *Gardeners' Chronicle* that the leaves of a species of *Eucalyptus* have been recently used on the Continent in place of lint, the leaves being merely laid on the wounds. "Their balsamic nature not only cures, but, after a few hours, all unpleasant odour ceases."

THE prickly poppy (*Argemone mexicana*), originally from the New World, has become naturalised throughout the tropics and sub-tropics of both hemispheres. In the West Indies, where it is very abundant, it is called *Fico del inferno*, the reason for this name being, according to Gerarde, "because of his fruit, which doth much resemble a figge in shape and bignesse, but so full of sharpe and venemous prickles that whosoever had one of them in his throte doubtless it would send him packing either to heaven or to hell." Barham, however, gives, as an explanation, a statement that the seeds, "being much stronger than opium," are "enough to send any that should take them wilfully to *inferno*;" but this is much exaggerated. In India it is now abundantly naturalised in the eastern part of the Punjab, and is spreading over fresh districts year by year. It is not altogether a useless addition to the Indian flora, as near Delhi an oil is extracted from the seeds which is used for burning, as well as in the treatment of chronic sores and eruptions.

ECONOMIC ENTOMOLOGY

THE Royal Horticultural Society has just offered the following prizes for collections of Economic Entomology:—

1. A prize of 10*l*. for the best collection of British insects injurious to any one plant, as the oak, pine, cabbage, wheat, &c. (the choice of the plant to be left to the competitor). The insects to be shown as much as possible in their various stages of development—eggs, larva, chrysalis, and perfect insect. In judging, a preference will be given to those collections which most successfully illustrate the life history of the insect, and exhibit the mischief done, whether shown by specimens, drawings, models, or other means. Examples of the application of drawings, models, and specimens to this purpose may be seen in the Society's collection in the South Kensington Museum.

2. A second prize of 3*l*. for the second best collection.

3. A prize of 5*l*. for the best miscellaneous collection of any branch of British Economic Entomology, similarly illustrated.

4. A second prize of 2*l*. for the second best collection.

The collections to be sent to Mr. James Richards, Assistant Secretary, Royal Horticultural Society, on or before the 1st of May, 1872, each collection bearing a motto, and a separate sealed envelope, with the motto on the outside, and the name of the competitor inside.

The Society is to be entitled to take from any of the collections sent in, whether successful or not, whatever specimens or illustrations they may choose, at a price to be fixed by the judges.

The judges to have power to refrain from awarding the prizes, should the collections seem not worthy.

SCIENCE TEACHING IN ORDINARY SCHOOLS

A PLAN for teaching the Natural Sciences in ordinary schools has been submitted to the School Board for London by Mr. J. C. Morris. The following are stated by the *Journal of the Society of Arts* to be the principal points of the proposed system:—Subjects—chemistry, heat, light, sound, electricity, magnetism, telegraphy, mechanics, hydrostatics, steam engine, &c.; geology, metallurgy, botany, zoology, animal physiology, health, &c A committee should be formed to select, revise, and compile a complete set of suitable text books, which should bear their sanction, and be then published in the cheapest possible form. There should be a depôt to provide apparatus at a cheap rate, a complete set of which, sufficient to illustrate the sciences mentioned, would not cost more than 100*l*., and should be divided into ten cases of 10*l*. each, a case to be complete for one or two subjects. The teacher should be a visting one. He could attend from two to three schools per day, and give from one to two hours' instruction in each, during two days in the week. The instruction to be given in a separate apartment, if there be one; or, if not, at such a time as would not interfere with ordinary school business. A single school teacher could thus attend from six to nine schools weekly, if sufficiently near each other, and get through at least three or four subjects annually, so that in two or three years he would have completed the full course in each school.

There should be an institution where teachers would have an opportunity of acquiring a practical knowledge of their profession, and affording a means of testing their qualifications. A more economical way, however, would be for each teacher to have an assistant, by which method a nucleus of teachers would soon multiply into a goodly number. In conclusion, Mr. Morris advocates periodical examinations, with a regular system of rewards; and, in reference to funds, he thinks that the teachers and inspectors might be supported either by Government or subscription, the apparatus to be supplied by Government at reduced rates. Schools should fix a small fee for attending the class, which would add to its importance, and help to defray expenses. Examination fees in like manner. Evening classes for adults could be managed under somewhat similar conditions.

THE INFLUENCE OF AQUEOUS VAPOUR ON METEOROLOGY

THE remarks on Meteorology contained in your summary of the scientific advances during the last year, encourage me to offer a few observations on the subject. Where so little is determined, speculations even by unknown contributors may receive some consideration. I shall begin with the subject of aqueous vapour, to which, I think, too much importance has in some respects been attached as a meteorological agent.

I shall commence by offering a determination of the specific heat of aqueous vapour at constant volume, which has not, to my knowledge, been hitherto given. It is evident that if a given weight of water be evaporated at 0° C., and then raised to 100° C., without change of volume, the total heat absorbed by it is the same as if it had been raised to 100° C. in the condition of water, and then evaporated so as to fill the same volume. Now if this amount be one kilogramme, and c be the specific heat of vapour at constant volume, the total heat absorbed in the first case is (adopting Regnault's formula for latent heat—viz., $L = 606^\circ{\cdot}5 - 0{\cdot}695\,t$)—

$$606^\circ{\cdot}5 + 100\,c.$$

And in the second case the equivalent amount is

$$537^\circ + 100{\cdot}8 = 637{\cdot}8,$$

the total amount of heat required to raise one kilo. of water from 0° to 100° C. being 100·8, according to the best determinations.

From this equation we obtain for the mean value of c between 0° C. and 100° C.

$$c = 0{\cdot}313$$

But the specific heat of aqueous vapour at constant pressure seems to be about 0·475. Hence for each kilo. of aqueous vapour raised through 1° C. at constant pressure, we have 0·313 heat units expended on internal work, and 0·162 on external work. The proportion is 1 : 0·517. In dry air the proportion in question, according to the latest determinations, seems to be 1 : 0·421. If the same amount of heat therefore be applied to produce expansion in vapour and in dry air, it produces a greater expansion in the former case. But the difference is not very material. In round numbers 30 per cent. of the absorbed heat is employed in producing expansion in one case, and 35 per cent. in the other. Apart from the different absorptive powers of air and vapour, this difference would be hardly perceptible. For equal quantities, heat absorbed by vapour has little (if any) greater effect in producing air currents or barometric depressions than heat absorbed by air. If the heat is absorbed in *producing* evaporation, the effect is still less. It is well known that less than one-eighth of the heat so absorbed goes to produce external work—a much smaller proportion than if it had been absorbed by dry air. I may observe that the result here arrived at for aqueous vapour supposes that its co-efficient of expansion between 0° C. and 100° C. is greater than that for air in the proportion of nearly 7 to 6. This would make the mean co-efficient about 0·00427 for 1° C. between these limits.

The next thing to ascertain is the quantity of aqueous vapour suspended in the air at any given time. This, of course, cannot be ascertained exactly, but it seems to me to be wholly erroneous to measure it by the tension of vapour at the earth's surface relatively to the pressure of dry air. It is generally supposed that the upper strata of the atmosphere are relatively drier than the lower; but even if we suppose them to have an equal relative humidity, the actual vapour-tension will become less in proportion to the tension of dry air at every step of the ascent. According to Sir J. Herschel, the law by which the temperature varies with the pressure of the air at any elevation is given (in Fahrenheit degrees) by the law

$$t = -87^\circ + 9{\cdot}0667\,p - 0{\cdot}1333\,p^2$$

Assuming this law, and supposing the relative humidity constant, we can calculate the temperature corresponding to any given pressure, and then find the corresponding vapour-tension by reference to the table. By trying this for each separate inch of pressure from 30 inches down to 0, and calculating the vapour-tension in each inch, I find (on a rough approximation) that the average proportion of the vapour-tension to the dry-air pressure will not exceed one-half of that which we find at the earth's surface. Thus, when the vapour-tension at the earth's surface is half an inch in 30 inches, or $\frac{1}{60}$, the average vapour-tension throughout the aërial column does not exceed $\frac{1}{120}$ of the whole; and when we calculate the weight of the superincumbent vapour, we must further allow for its smaller specific gravity. Making this correction, I believe that when the tension of vapour at sea-level is half an inch, the real weight of the superincumbent vapour-column seldom exceeds that of one-sixth of an inch of mercury. The proportions of course are not fixed. Those which I take from Herschel answer best for a temperature at the earth's surface of about 65° F., or 18° C.

I intend to apply these observations chiefly to the explanation of the annual and diurnal variations of the barometer by the greater or less amount of aqueous vapour in the air. It is supposed, for example, that when the vapour-tension at the earth's surface is an inch, about $\frac{1}{30}$ of the whole air-column consists of vapour. This displaces an equal bulk of air, and thus the column is lighter than a dry-air column of the same height and temperature by the difference in weight of the air and vapour occupying this space, *i.e.* about $\frac{3}{8}$ of an inch, or $\frac{1}{80}$ of the whole. But if my computation is correct, the diminution of weight owing to this cause would only be $\frac{3}{16}$ of an inch, or $\frac{1}{160}$ of the whole. Taking the standard pressure at 30 inches, this would only account for a diminution of 0·187 of an inch when the air from being absolutely dry changed to one inch of vapour-tension. In this country we never experience absolute dryness, and we seldom if ever experience so much as an inch of vapour-tension at the surface. Yet the annual variations of the barometer exceed 0·187 of an inch. Looking, for example, at the table for Greenwich Observatory at the end of Herschel's work, I find the mean monthly pressure varying between 29·923 and 29·602 inches, a difference of 0·321 inches; while the monthly means of vapour-tension vary between 0·466 and 0·195, a difference of 0·271; which, as I have endeavoured to prove, would only account for a change of 0·051 in the mean pressure. The diurnal maxima and minima at the same place exhibit a difference of 0·018, the vapour-tension giving 0·042, which only accounts for about 0·008.

The same thing is more evident in other places. At Madrid for example, the monthly barometric averages vary between 28·003 and 27·701, a difference of 0·302, while the vapour-tension varies between 0·236 and 0·076, a difference of 0·160. At Longwood, St. Helena, the diurnal variation of the barometer gives a mean of 0·067, while that of the vapour-tension is only 0·030. This would only account for a change of 0·006, or less than $\frac{1}{10}$ of the actual change. At Bombay the diurnal variation of the barometer amounts to 0·102 inches, while the corresponding variation of vapour-tension is only 0·004. This would not account for one hundredth part of the change.

The same result is confirmed by taking another view. It is pretty evident that in a country of any considerable extent the diurnal oscillation of the barometer (which is often nearly double the diurnal variation), if produced by changes of vapour-tension, must always be less than the mean diurnal rainfall and dew-fall, since rain often falls at hours when the barometer is on its diurnal descent. Now in this country the mean diurnal rainfall does not exceed $\frac{1}{15}$ of an inch, corresponding in weight to $\frac{1}{200}$ of an inch of mercury. Supposing all this to fall during the hours when the mean barometric pressure is increasing, the subtraction of that amount of aqueous vapour from the column, and the replacing of it by air, would not nearly account for the observed diurnal oscillations.

I therefore conclude that the annual and diurnal variations of the barometer are not due to changes in the amount of vapour present in the aërial column. Indeed it does not seem certain that the vapour displaces air at all. It may simply permeate that column without displacing any of it, and thus add to the weight of it. Again, if it displaced air, condensation or the formation of dense clouds ought always to be attended with a rise in the barometer, since air would rush in to fill up the space which the vapour vacated on condensing. This does not seem to be the case.

W. H. S. MONCK

THE ROYAL SOCIETY OF VICTORIA

WE owe an apology to our scientific friends at the Antipodes for having allowed the president's address, delivered last July, to have remained so long unnoticed. Mr. Ellery, after noticing the most important papers that had been read during the past two sessions (for no address was delivered in 1870 in consequence of alterations being made in the Society's buildings), including eight on physical science, seven on geology, mineralogy, and palæontology, one on natural history, three on medical science, one on social science, and four on arts and manufactures, expresses his regret that the state of their finances has for a time caused a stoppage in the printing of their Transactions which were commenced in 1868. He then proceeds to notice the present state of the chief scientific establishments in Victoria. "Botanical knowledge," he observes, "is largely indebted to the labours of our member, Dr. Von Müller, the head of the botanical department of Victoria. One of the prominent results of Dr. Müller's investigations is the publication of the *Universal Flora of Australia* (under the editorship of Mr. Bentham), to which Dr. Müller is the principal contributor; the fifth volume has, by this time, passed the press in London. This work, when completed, will be the only one extant that deals universally with the flora of a large division of the earth's surface. It will form a permanent basis of all future research with respect to the adaptability of Australian plants to medicine, the arts, or other useful purposes. You will be glad to learn that Dr. Müller is about to establish a permanent phytological collection in our new industrial museum, which will comprise objects illustrative of our natural resources in the vegetable kingdom, and of materials used in the industries obtained from plants in this country as well as other parts of the globe. Such a collection properly arranged and accessible to the public will undoubtedly prove a valuable and instructive addition to the industrial museum, more especially if at the same time Dr. Müller fulfils a project he has in contemplation of publishing in a popular form a volume on the culture of utilitarian plants in the colony not indigenous to it, as well as of plants likely to add to the resources of countries lying under similar latitudes to our own. The preservation and perpetuation of our more extensive forests has already become a question of serious import. A few years ago we thought our forests inexhaustible; but already the bad effects of the indiscriminate stripping of our mountain ranges are becoming visible. The immense and increasing draft on our forests for fuel and other purposes has already denuded the land in the vicinity of towns and other centres of population of its former covering of timber. This, unless replaced by artificial planting, will eventually leave our hills bare, and in all probability the climate will suffer in proportion. Dr. Müller, in introducing and rearing very large numbers of forest trees that will be useful in themselves for the wood and bark, has exercised a wise forethought, of which the colony will reap the fruit in years to come, when the corks, oaks, hickories, red cedars, and firs, shall have in part replaced our eucalypti, mimosæ, and other far less useful trees."

"Our observatory," he adds, "has been engaged with its usual work in astronomy, meteorology, terrestrial magnetism, and general physics. Considerable progress has been made in the Melbourne portion of the survey of the southern heavens; the sky lying between the 60th and 52nd parallels of declination has been carefully surveyed, and the positions of 38,305 stars established and catalogued, of which 29,633 have been reduced to the epoch agreed upon, namely, 1875, and their positions at that date computed. Our staff of self-registering meteorological instruments may now be considered complete, and consist of three magnetographs (that is for declination, dip, and horizontal intensity), a thermograph, a barograph, electrograph, and anemograph. With these instruments a continuous and unceasing record is obtained by the aid of photography of all the variations in the force and direction of the earth's magnetism, of the temperature of the air, and of evaporation, of the state and variations of the pressure of the air, atmospheric electricity, as well as of the direction, changes, and force of the wind."

The great Melbourne telescope, which, when the address was delivered, had been fairly at work for ten months, is then considered, and Mr. Ellery observes that while the Society is disappointed in not getting, as it was hoped, the best telescope in the world, the members may feel satisfied that they have obtained an instrument that, "if it does not exceed, quite equals every other of its sort that has been yet made."

The progress of the survey is then noticed at considerable length. "The coast line from the boundary of South Australia to Lake Howe has been carefully measured, and, with the exception of the north-west portion of the colony, nearly every district has been emmeshed by the geodetic surveyors. The most important operation of late has been the determination of the termini of the boundary between New South Wales and Victoria." It is much to be regretted that the late retrenchments in the public expenditure have materially interfered with the progress of the survey.

After a few remarks on the commercial importance of local industries, especially the preservation of meat, the president referred to our vastly increased knowledge of the sun since the date of the eclipse of May 1869, to the nature of the sun's spots, and to the connection of the latter with the occurrence of magnificent auroras and magnetic storms, and to the spectrum of auroral light. "During the most brilliant display in April last, I was able," he observes, "to obtain a very bright spectrum of the light with a micro-spectroscope. Unfortunately the dispersion was small, but the light was so intense as to admit of a very narrow slit. The spectrum obtained from the red streamers consisted of a strong red band or line (which I estimated was rather more refrangible than C line), and bands in the green, which I believe to be the same as described by Angström. The spectrum of the green light which formed the lower arch of the aurora, however, contained no red band, and the appearance of it, as the spectroscope was passed up and down, so as to receive the light from the streamers or green arch, was very marked indeed. I am not aware of this red band or line having been noticed by any previous observers; and had it not been so clear and prominent, far brighter than the green ones—and had I not proved that it belonged to the red streamers, and not to any other, of the auroral light, by the method referred to—I might have been doubtful as to the real existence of a line not hitherto noted in the spectra of aurora." The address concludes with a few observations regarding the possibility of our ever being able to ascertain the laws which govern the weather so as to predict with certainty the atmospheric condition of to-morrow. On this point Mr. Ellery does not express himself very hopefully, but he thinks that the greater climatal events, such as dry or wet, hot or cold, seasons may be traced to varying conditions in the sun itself, and will be found to be extraneous to our globe.

G. E. D.

SCIENTIFIC SERIALS

THE *Journal of the Royal Geological Society of Ireland*, vol. xii. Part 3 (vol. ii. Part 3, new series), containing the Proceedings of the Society for the session 1869-70, has just been published. It contains among other memoirs, Prof. Traquair on *Griffithides mucronatus* (M'Coy) Plate xvi., and on *Calamoichthys calabaricus*. Rev. J. D. La Touche on Spheroidal Structure in Silurian Rocks, Plates xvii.-xx. Rev. M. Close on some Corries and their Rock Basins in Kerry, Plate xxi. Edward Hull on the Geological Age of the Ballycastle Coal-field, and its Relations to the Carboniferous Rocks of the West of Scotland, Plate xxiii. W. H. Baily on the Fossils of the Ballycastle Coal-field, Co. Antrim.

Zeitschrift für Ethnologie, 1870, Hefts 3, 4.—A paper by Bastian on the legend of the Amazons, is full of valuable information, but is written with less skill than learning. The footnotes make more than three-fourths of the whole, and the parentheses nearly half of the rest.—Hensel contributes a description of two skulls of Coroado Indians (Brazil) with figures. He agrees with many of our best ethnologists that the dimensions of the cranium afford us no safe ground for making racial or specific distinctions. On the other hand, he regards the structure of the facial bones as of great importance from this point of view.—R. Hartmann continues his studies on domestic animals by an account of the reindeer in its present condition, followed by an interesting discussion on the evidence of its domestication in prehistoric times. This number also contains a short archæological account of the Uglei See (one of the numerous lakes in the east of Holstein, situated in an enclave belonging to Oldenburg), by E. Friedel.—The last number of the same journal (1870, 4) is almost entirely devoted to American Ethnology. Prof. Strobel concludes his contributions to comparative ethnology by an account of the weapons and food of the South American Indians; Dr. Fonck has a paper on the Indians of Southern Chili; Ernst of Carácas one on the Natives of the Peninsula of Goajiro, which forms the western boundary of the entrance to the gulf and bay of Maracaybo, in Columbia; and Erman contributes an account (with a map) of the various races inhabiting what was until lately Russian America, the Aleutian Isles, and the opposite coast of N.E. Asia; he divides them into two great groups according to their system of numeration.

IN the *Journal of the Ethnological Society of London* (October 1870) is an interesting paper by Mr. David Forbes "On the Aymara Indians of the Peruvian highlands." Very full information as to their physical structure is given, together with *exact measurements*. Beside their short stature and capacious thorax (which seems to be constantly fixed in the condition of inspiration) Mr. Forbes's statistics show that the thigh is shorter than the leg, and that the heel is as much shorter than a European's as a Negro's is longer. The half-castes between these Indians and the white population are not believed by the author to be prolific, so that, as in the case of mulattos, the intermediate race would soon die out if not continually recruited by new accessions. Among many interesting details on the food of the Aymaras—especially their method of preparing potato so as to keep it from rotting—on their disposition and habits, their implements, and their language, perhaps the most remarkable is an account of a silver statuette (figured in pl. xx.) of a man in a strange headdress, who holds in one hand a mask, which he has apparently taken off in order to look through an instrument like a telescope. This tube he holds to his left eye (without shutting the other) and directs it upwards. Mr. Forbes believes this to be a unique specimen.

THE last part (Band vii. Heft 1) of the *Zeitschrift für Biologie* contains: 1. The results of an elaborate series of experiments by Gustave Meyer of Oldenburg on the effects of feeding dogs and man on bread alone, and bread mingled with meat and other articles of diet. He shows what indeed has long been known, that to feed either animals or man on bread alone is a great waste of material, and that immense quantities must be given in order that the body should lose no flesh, whilst on the other hand the addition of some, even though a small quantity, of meat is economical. He demonstrates that the tissues of the body become more watery with insufficient food, which renders the whole organism less capable of resisting injurious influences. In his experiments on man he endeavoured to ascertain which of the several kinds of bread in ordinary use (white bread, rye bread, black bread) was absorbed in greatest amount during its passage through the alimentary canal, and found that white wheaten bread occupies the first place, then leavened rye bread, then the bread (rye) prepared by the Horsford-Liebig process, and lastly the Pumpernickel (North German black bread). Nevertheless, the first is not so satisfying to the feeling of hunger as the three latter, and is more expensive in every point of view. He denies the great nutritious value often attributed to bran, since the nitrogenous compounds it contains are mingled with much non-assimilable matter, but admits that if these could be extracted and were then returned to the flour, the best results would be obtained, as the meal already contains abundance of salts. 2. A paper by MM. Ernst Schulze and Max Märcker on the determination of Nitrogen in the Urine of the Ruminants. 3. A paper by Dr. J. Bauer on the Metamorphosis of tissue in poisoning with Phosphorus; and lastly a short paper by Max von Pettenkofer on Typhus and Cholera as connected with the basal water line in Zurich.

SOCIETIES AND ACADEMIES

LONDON

Chemical Society, April 6.—Prof. Frankland, F.R.S., president, in the chair. The president, occupying the chair the first time since his election, returned his thanks to the Society for the honour conferred upon him, and expressed his readiness to discharge the duties of his office to the best of his abilities. The following gentlemen were elected fellows:—F. Coles, C. E. Groves, E. W. T. Jones, L. T. MacEwan, and J. L. Shuter. The following papers were read: "On Burnt Iron and Burnt Steel," by W. Mattieu Williams. Iron, which has been damaged by reheating, or excessively heated and exposed after balling in the puddling furnace, is designated "burnt iron" by the workmen. It is remarkable that no amount of heat applied to the iron in the blast furnace or in the early stages of the puddling process produces burnt iron. Burnt iron is brittle, its fracture is short and what is called crystalline, it has lost the fibrous character of good iron. If steel is raised to a bright red heat and suddenly cooled, it is rendered hard and brittle, but these conditions may be modified by the process of tempering; if, however, the steel be raised to a yellow or white heat, and then be suddenly cooled, it is no longer capable of being tempered by mere reheating. It is worthless for ordinary uses of steel unless it is again raised to a welding heat and rolled or hammered while hot, and then allowed to cool gradually. The fracture of burnt steel presents a coarse grain and a crystalline appearance. Careful investigation, however, shows something more, viz., that the facets of the aggregated granules have a more or less conchoidal form. The name of "toad's eyes" has been given by practical men to these concavities. Mr. Williams found that a piece of burnt iron contained oxide of iron dispersed through its mass. A sample of burnt steel, however, investigated in the same manner as the iron, showed no indications of the presence of oxide. This, of course, was to be expected, as the carbon of the steel must, more or less completely, protect the metal from oxidation. That iron, when unprotected by combined carbon, should oxidise not merely on its surface, but through its whole substance, when exposed at a sufficiently high temperature and for a sufficient length of time to the action of the atmospheric oxygen, is not difficult to conceive, since the researches of Deville, Troost, and Graham have shown red-hot iron to be permeable by certain gases. In the case of steel, as Mr. Williams states, the burning is limited to the oxidation and consequent removal of the carbon, which takes place even at a low red heat. The permeability of red-hot steel by oxygen and carbonic oxide enables us to understand the process of the internal oxidation of the carbon. The "toad's eyes" or conchoidal facets of the so-called crystals, Mr. Williams explains by supposing a piece of steel at the temperature most favourable to the rapidest endosmosis of oxygen and the exosmosis of carbonic oxide to be suddenly cooled, and the possible occlusion of the carbonic oxide to be arrested. The results would be a certain molecular disintegration and porosity of the steel presenting those conchoidal spots. This view is further supported by the fact that burnt steel may be cured by reheating and hammering, or rolling at a welding heat.—"On the Formation of Sulpho-acids," by Dr. Armstrong. Occupied with an investigation into the constitution of sulphuric acid, the author turned his attention to chlorhydric sulphate, a body discovered some years ago by Prof. Williamson. When that substance, SO_2 HO Cl, is made to react on benzol, the chief product of the reaction is sulphobenzid; sulphobenzolic chloride and sulphobenzolic acid being also formed, but in relatively small quantity. This led Dr. Armstrong to commence a series of experiments to determine, if possible, the conditions under which the one or the other of the above reactions took place, and to arrive at a general expression for the action of chlorhydric sulphate on organic bodies. The bodies he had until now acted upon with SO_2 HO Cl are brombenzol, nitrobenzol, nitrophenol (both modifications, the volatile and the non-volatile), and naphthalin. The results of his experiments lead the author to conclude that the normal action, so to speak, of SO_2 HO Cl is to form a sulpho-acid, the Cl of the chloride removing H from the body acted upon, and replacing it by the group HSO_3; it is only under certain conditions that both Cl and HO are removed from the chloride, and a sulphobenzid-analogous compound formed. What these conditions are Dr. Armstrong hopes to establish by further experiments.—"On a Water from the Coal Measures at Westville, N.S.," by Prof. How. The contents of this paper bear upon the relation of the constitution of a water, and the nature of the geological stratum from which it takes its origin. The water above-mentioned comes from what Dr. Dawson terms the Middle Coal Formation of Nova Scotia, which includes the productive beds of coal, and which, according to the same authority, are destitute of properly marine limestone. The analysis of the water seems to bear out the latter assertion, since the water is very poor in chlorides.

Geologists' Association, April 4.—The Rev. T. Wiltshire, M.A., F.G.S., president, in the chair. A paper by Messrs. Alfred and R. Bell was read, "On the English Crags, considered in reference to the Stratigraphical Divisions indicated by their Invertebrate Fauna." In this paper the authors object to the present division of the crag series, and especially to all the beds which have hitherto been included under the term Red Crag being associated together. From palæontological and other evidence they conclude that the upper portions of the Red Crag ought to be associated with the Mammaliferous Crag, the Chillesford beds, &c., for the whole of which deposits the name Upper Crag is proposed. The Red Crag proper should then be called Middle Crag, and for the term Coralline Crag the name Lower Crag should be substituted. The authors having paid great attention to the organic remains of the crag, were able to give with their paper lists in which were enumerated a larger number of species from the Red Crag than had previously been published. Mr. Henry Woodward, F.G.S., while commending the labours of Messrs. Bell in the Red Crag, urged the systematic exploration of the Norwich Crag, which would, he thought, yield interesting and valuable results. Communications which had been received from Mr. G. Charlsworth and the Rev. Osmond Fisher on the subject of the paper were read, and after some remarks by Mr. Lobley on the nomenclature at present in use, Prof. Morris, in an interesting speech, referred to the labours of Mr. Charlsworth and others, and advised the postponement of any alteration of the crag nomenclature until the recent researches of Mr. Prestwich have been published. Several other members took part in the discussion, after which Mr. A. Bell briefly replied.—A paper on South African Diamonds was then read by Prof. Tennant, who exhibited a fine collection of specimens of these brilliants, as well as models of the largest which have been found. Amongst the interesting facts stated it was pointed out that in four years six diamonds, each weighing upwards of fifty carats, had been found in South Africa, while in the same period only one of a similar weight had been obtained from Brazil. The president expressed his belief that diamonds would ultimately be produced artificially. Prof. Morris inclined to the opinion that diamonds were of vegetable origin, and thought they might have been produced from decomposed resins. The geological formation from which diamonds are derived is very doubtful, as the stones are found in gravels and sands brought down by streams. Mr. Rabone, who has lately returned from the diamond-fields, gave a very interesting account of the discovery of diamonds in the colony, and of the operations now going on there. It appears that no less than 150,000*l*. worth of diamonds have been passed for duty, and this amount, there is reason to believe, is not more than half of the entire value of the stones found during the past four years. The diamond country is, perhaps, 20,000 square miles in extent, and there are now 13,000 persons engaged in searching for the gems. Mr. Rabone expressed his conviction that after two or three months' labour success on the part of a searcher was certain, and corroborated Prof. Tennant's statement as to the large proportion of heavy diamonds found. He considered the discovery of diamonds in South Africa was intended to further the spread of the human race, reminding the meeting that the colony of South Africa is larger than France, while the population is not greater than that of the city of Glasgow.—At the next meeting of the association on the 5th May a paper will be read by Mr. Henry Woodward, F.G.S., F.Z.S., "On the Fauna of the Carboniferous Epoch."

Norwich

Norfolk and Norwich Naturalists' Society, March 31.—Mr. H. Stevenson was elected the President for the ensuing year, and the Rev. Joseph Crompton, who has filled the chair since the formation of the society, was elected a Vice-President. Mr. Thomas Southwell was elected secretary, and Mr. C. G. Barrett treasurer. The retiring President then read an interesting address, setting forth what had been done by the society during the past year, and what should be its objects in the future, contrasting favourably the present state of scientific inquiry and the spirit in which the search after truth is received, with that which prevailed in years that are passed, concluding with some remarks upon Darwin's last book, the "Descent of Man," which he said should rather have been called the "Ascent of Man."—After the President's address, a letter was read from Mr. Stevenson, who was unable to be present, strongly reprobating the practice of killing woodcocks in spring, when returning northwards to their accustomed breeding haunts. He deprecated the act as inexcusable, inasmuch as a March woodcock is useless for the table, and the shooting season being over, they are mostly killed by gamekeepers, whereas, if the birds were allowed to remain unmolested, many would breed in this country, every season affording fresh instances of their inclination to do so.

Kilkenny

Royal Historical and Archæological Association of Ireland, April 5.—Mr. P. Walters in the chair. The following new Associates were elected:—Rev. F. E. Hamilton, Messrs. R. O'Brien, R. W. Banks, W. F. Skene, J. H. Browne, J.

J. Cramsie, W. E. B. Wyse, T. Atkinson, J. O'Neill, and J. Martin, M.D. The following members were admitted as Fellows:—Hon. B. E. B. Fitzpatrick, Lieut.-Col. E. Cooper, Captain Langton, Messrs. E. Shine, R. R. Brash, J. Watson, N. Ennis, J. Digges, F. Coney, J. Hill, J. E. Mayler, and W. R. Molloy. An application from Mr. Justin McCarthy Brown, Hobart Town, Tasmania, "that the Journal of the Association might be given as a free grant to the Tasmania Library, Hobart Town," was considered and granted. The Secretary, Rev. James Graves, reported on the progress made with the restoration of St. Francis Abbey, Kilkenny, and pointed out the necessity for further subscriptions to preserve the beautiful old tower. A report on the present state of the ruins at Monasterboice, Co. Louth, by J. Bell, C.E., was read, and the following subscriptions, to commence forming a preservation fund, announced:—E. Fost, Bart., D. Dunlop, R. M. Bellew, C. Fortescue, M.P., and M. O'Reilly-Dease, M.P., 10*l.* each; M. Branagan, 5*l.*; Revs. Harpur and Campbell offered not only to subscribe but also to collect subscriptions. The Chairman exhibited and described some more of the ancient record of the Corporation of Kilkenny.—Papers read:—"On the exploration of Cranoges," by G. H. Kinahan, M.R.I.A., "On some iron tools and other antiquities found in the Cranoge of Cornagall," by W. F. Wakeman, M.R.I.A.

CALCUTTA

Asiatic Society of Bengal, January 4.—The president, the Hon. T. B. Phear, exhibited some diagrams, showing the diurnal oscillations of the barometer at Dalhousie during part of October 1870. He remarked upon these curves, and called attention to the part which the pressure of vapour in the atmosphere was supposed to have in effecting the barometric oscillations. Colonel Strachy stated that the opinion that the presence of vapour in the atmosphere had any important influence on the oscillations of the barometer was totally unfounded, and indicated the results of his own observations at various stations.—Mr. T. W. H. Tolbort communicated a paper on the history, archæology, and natural productions of the district of Dera Ismail Khan, which will be published in the Journal of the Society.—Bábu Rájendrál ıla Mitra read a memoir on the antiquity of Indian architecture, in which he maintained the indigenousness of the art.—Mr. Wood Mason exhibited and described a very curious instance of polydactylism in a horse from Bagdad. This horse had on each fore-foot a supernumerary digit, furnished with an asymmetrical hoof, articulated to the rudimentary metacarpals of the fourth toes; these digits consisted of the usual number of phalanges. Figures of this curious malformation are given.

PHILADELPHIA

Academy of Natural Sciences, December 6, 1870.—Dr. Ruschenberger, president, in the chair.—Professor Cope made some observations on a number of species of reptiles from the Cretaceous beds of Kansas, which he had recently studied. He tated that the specimens included parts of *Elasmosaurus Latyurus* Cope, *Polycotylus latipinnis* Cope, *Liodon proriger* Cope, and two new Liodons, which he named *L. ictericus* and *pl. mudgei.* A third new Mosasauroid of the size of the *L. Mudgei* was described under the name of *Clidastes cineriorium.* It was stated to be much the largest species of the genus, and to differ from the three now known in having the plane of the articular extremities at right angles to the long axis of the centra, and not oblique to it. He described a third new Liodon, of gigantic size, stating it to exceed by very much the Maestricht reptile, and even the *Mosasaurus brumbzi* Gibbes, which was till now the largest known species. He pointed out the characters of the vertebræ, which were very much depressed as to the centrum, which measured 5¾ inches in diameter. It was allied to the *M. brumbzi*, but differed in having a strong emargination of the articular faces to accommodate the neural canal. He named it *Liodon dyspelor.* Prof. Cope also exhibited the humeri and femora of *Polycotylus*, which were like those of *Plesiosaurus*, and measured eighteen inches in length.—Mr. Thomas Meehan exhibited several specimens of the *Maclura aurantiaca*, the common osage orange, in which the plants were inarched together in pairs in a remarkable way. He said the osage orange was extensively grown as a hedge plant, and in digging up the one-year plants these united twins were usually found in the proportion of about one score in ten thousand. Double kernels were common occurrences in many seeds. There were double peaches, almonds, and double yolks in eggs. But these all had their separate seed coverings or membranes, and the yolks their own albuminous envelopes, consequently the separate embryos produced distinct plants. But these indicated that there had been two separate embryos under one seminal covering, and that the radicular portions of this double embryo, having no membrane to separate them, had inarched themselves together while passing to the ground. If this was the true explanation, he thought there was no such case recorded. That it was true seemed probable, from the fact that all the specimens were united in exactly the same manner, showing that time, place, and the circumstances of the union were uniformly the same. The scars showed that there were four cotyledons and two germs, and that the place of union was midway between the pairs of cotyledons. From the base of the cotyledons extending the whole length of the radicle, the union existed. The length of this united part was from half an inch to one inch, according to the vigour of the plant. Another lesson he thought was afforded by these specimens. Dr. Asa Gray had recently remarked, in *Silliman's Journal*, that European botanists still believed what American botanists had learned to doubt, that the radicle was a true root, rather than a morphologised joint of stem. Here was, he believed, an illustration of the American view. These radicles, which had evidently united together under the seed coat, had elongated after protrusion, just as a young shoot with all its parts formed in the bud elongates after the bursting of the bud scales. They comprised the half inch, or inch united portions before referred to. If these radicular portions of the seed were of the nature of root rather than of stem, we might expect to see lateral fibres push from them, as we do see from the true roots, which start out below the union. But these parts are as free from rootlets as any portion of the true stems above the cotyledon points, indicating, as had been suggested, that their properties were rather of stem than of root.

December 20.—Mr. Vaux, vice-president, in the chair.—Prof. Leidy directed attention to a preparation of the trunk of an adult male subject, from the dissecting room of the University, in which all the viscera were reversed in the order of their usual position. The heart is reversed in position with its apex directed to the right. The aorta descends on the right side; and the cavæ are placed on the left of the vertebral column. The liver is placed in the left, the spleen in the right side. The stomach is reversed, and the large intestine commencing in the left iliac region terminates in the rectum from the right side.

December 27.—Dr. Ruschenberger, president, in the chair.—Prof. Leidy called attention to an interesting geological phenomenon in the vicinity of Wayne station on the Germantown Railroad, about three miles from Philadelphia. At the point where Wayne Street cuts through a fold in the micaceous schists of this district, there occur huge imbedded boulders of very hard compact hornblende rock. The matrix of mica schist has the appearance of an altered argillaceous slate, and rapidly decays on exposure. The hornblende rocks are thus left protruding above the soil, and would be difficult to account for if attention had not previously been called to them in place. As occurring in the schist, they are rounded upon their corners and edges, and smooth upon the sides. It does not appear an improbable conjecture to suppose that they constituted a part of a primitive surface formation—perhaps the original earth crust—which was broken up before the deposition of the metamorphic rocks which make up the azoic rocks of undetermined geological age, overlying the south-eastern angle of Pennsylvania; and that by steam and current actions, perhaps in part by glacial, they were brought into the shape of boulders at a time anterior to the deposition of the sedimentary mica schists. And it is a fact of interest in this connection that the highly garnetiferous mica schists of this district, are charged with dodecahedral garnets, which have probably belonged to preexistent rocks, inasmuch as their angles and edges are rounded off, and the crystals reduced to an almost globular form. This is true of the garnets while still firmly imbedded in the mica schists, and applies to the garnetiferous mica schists extending over a wide area.

American Philosophical Society, February 17.—Dr. Emerson read a paper on the Lunar Influence in its supposed relation to meteorological phenomena, combating views favourable to the existence of such influence.

March 3.—Prof. Cope read a paper "On the occurrence of fossil Cobitidæ in Idaho."—A paper by Thomas Bland was read

"On the geology and physical geography of the West Indies, with reference to the distribution of mollusca." He stated that the land shell faunas of Porto Rico and the Virgin Islands, Sombrero, Anguilla, St. Martin, and St. Bartholomew, are closely allied, and may be called distinct from that of Haiti on the west and the islands to the south. He came to this conclusion from the facts of distribution, and now finds corroborative evidence from the depth of water. An elevation of the bank on which Porto Rico and the Virgin Islands stand (to and including Anegada) of less than 40 fathoms would make one island of the whole. Anguilla, St. Martin and St. Bartholomew stand on one bank, and a similar elevation would unite them; there is deep waters around Sombrero. The fauna of the group is Mexican and Central American, with peculiar genera not represented in the islands south of the Anguilla bank. There are genera represented in Cuba and the Bahamas, Haiti, Porto Rico, and the islands on the Virgin and Anguilla banks, but not in the islands south. One Strophia fossil in Sombrero and in St. Croix, recent in the others. The depth of water between St. Thomas and St. Croix is 2,000 fathoms, telling of long separation. These facts point to a large island or continent, which embraced the Anguilla bank in its southern limit. Barbuda and Antigua stand on one bank, St. Eustatius, St. Kitts, and Nevis on another, with land shell fauna alliance with Guadaloupe, Dominica, Martinique, and Barbados—that group by their fauna connected (not a few species in common) with Guiana—water over 1,000 fathoms deep between Dominica and Martinique, and the latter and St. Lucia and St. Vincent. Now Trinidad and Tobago (both on soundings) Grenada (300 to 400 fathoms between it and Trinidad), the Grenadines (all on one bank with Grenada), and St. Vincent (1,300 fathoms between it and St. Lucia) have peculiarly the fauna of Venezuela. Bulimus proper (South American) is only found on those islands and St. Lucia. The greatest depth between St. Vincent and the Barbados is 1,218 fathoms, and between the latter and Tobago 1,060. These facts point to an extension of the South American continent, say from north of the Amazon River to a point west of Trinidad, and northerly to Barbuda, the west side (now Trinidad, Tobago, Grenada, Grenadines, St. Vincent, and St. Lucia), having the Venezuelean fauna, and the east side (now Barbados, Martinique, Dominica, Guadaloupe, Antigua, &c.) having the Guiana fauna—Prof. Cope read a paper entitled "Supplement to the Synopsis of Extinct Batrachia and Reptilia, &c.," in which several extinct reptiles were described. Portions of the jaws and teeth of one of these from New Jersey were exhibited. It was named *Liodon sectorius*, and was characterised by a greater amount of compression of the teeth than in any certainly known Mosasauron, the crown resembling those of some sharks.—Prof. Cope read a paper "On extinct forms of fishes of the neotropical region." Two new genera, *Prymnates* (Clupeidæ) and *Anædopogon* (? Characinidæ) were determined. He also exhibited some fossil Batrachia from the Carboniferous of Linton, Ohio, obtained by the Geological Survey under Prof. Newberry. One a specimen of *Sauropleura remex* Cope presented a well-developed hind limb. *Oestocephalus amphiumimus* was branchiferous, and probably limbless. Another fossil, representing a new genus, was referred to as *Conchiocephalus piscinus* Cope. It had two operculum-like bones on the sides of the cranium, the teeth obtuse and in brushes; the size of *Protonopsis*.—Mr. Pliny Earle Chase read a paper on American and European rain-falls, showing an opposition at different seasons of the year, analogous to that which he had pointed out at different periods of the lunar month. Comparing the quarterly rains at Lisbon and at Philadelphia for the sixteen years, 1855 to 1870 inclusive, he found that the half years which were the most rainy at one station were the least so at the other. He also found that, in ten years out of the sixteen, an annual rainfall above the average at one station was accompanied by one below the average at the other. Mr. Chase also communicated some of the results which he had obtained by a discussion of the meteorological observations of the Signal Service Bureau, United States War Department. Perhaps the most important of his deductions were the following:—(1) The greater importance of the barometric gradients than of the isobars, in making American forecasts; (2) the great frequency of anti-cyclonic storms in the United States; (3) the probable origin of a large proportion of our storms in the blending of the polar and equatorial currents, near the latitudes at which the general tendency of the winds changes its direction; (4) the greater severity and briefer duration of cyclonic commotions than of those which are primarily anti-cyclonic.

THE HOPE OF FRANCE

A PAPER which M. Henri Sainte-Claire Deville has recently laid before the Paris Academy of Sciences is in our opinion of such high importance that we make no apology for placing it in original before our readers. It runs as follows :—

"La science a joué un grand et terrible rôle dans les défaites que nous venons de subir. Les découvertes d'Ampère, les travaux de nos mécaniciens militaires ont été cruellement utilisés contre nous. Enfin, l'organisation libérale des universités allemandes a été mise au service de passions haineuses dirigées contre notre pays. Aussi dit-on de tous côtés et avec raison que c'est par la science que nous avons été vaincus. La cause en est dans la régime qui nous écrase depuis quatre-vingts ans, régime qui subordonne les hommes de la science aux hommes de la politique et de l'administration, régime qui fait traiter les affaires de la science, leur propagation, leur enseignement, et leur application par des corps ou des bureaux où manque la compétence et par suite l'amour du progrès.

"Aujourd'hui, messieurs, il est temps d'agiter publiquement les grandes questions. La réserve modeste pratiquée trop souvent par un trop grand nombre des membres de cette Académie serait une faute grave en ce moment, une faute sans excuse.

"Dans des temps calmes beaucoup d'entre nous avaient pu se ménager dans leurs cabinets ou leurs laboratoires cette vie studieuse rendue si douce et si facile par l'éloignement des hommes et de leurs débats intéressés. Il est de notre devoir aujourd'hui d'intervenir tous activement et directement dans les affaires du pays, et de contribuer de toutes nos forces à une régénération par le savoir dont la France exprime partout la nécessité.

"Dans les temps difficiles, le pays a trouvé chez les membres de cette Académie, et dans l'Académie tout entière, le dévouement absolu sur lequel il avait le droit de compter. Nos séances, si bien remplies pendant la durée du siége, en seront un témoignage mémorable. Ces services mêmes, l'autorité morale que nous devons à notre origine qui est l'élection de chaque membre par ses pairs, tout, messieurs, nous oblige de contribuer à cette régénération du pays par l'initiative de chacun, par l'action de la compagnie tout entière.

"J'ai donc l'honneur de proposer à l'Académie d'admettre à l'ordre du jour de ses séances les grandes questions du développement et de l'enseignement de la science en France et toutes les questions d'intérêt général qui concernent la science et les savants.

"Par exemple, la France possède de grands et glorieux corps scientifiques dont quelques membres ont constamment siégé dans cette Académie. Quel service nous rendrions, si nous pouvions faire dépouiller ces grands corps de l'enveloppe politique, administrative ou fiscale qui les étouffe, qui met en péril le recrutement de la science parmi eux et dans les écoles célèbres qui leur servent de pépinières.

"Je le répète; je demande à mes confrères d'élargir le cercle de ses communications et d'y faire entrer toutes les questions d'intérêt scientifique, de quelque ordre et de quelle que nature qu'elles soient, de quelque part qu'elles viennent.

"Des commissions choisies dans nos sections et quelquefois dans les autres classes de l'Institut, devraient préparer, résumer et rédiger au besoin comme des vœux ou des décisions académiques les délibérations de la compagnie.

"Sous cette forme nouvelle, qui exclut toute intervention dans les affaires du gouvernement (car les affaires d'instruction publique ne sauraient plus être politiques), nous ferons arriver les conseils de l'expérience et du savoir, et, j'espère, toutes les vérités utiles à la connaissance directe du pays tout entier."

It is not our purpose to inquire how true may be M. Deville's idea that the success of the German arms has been due to the more vigorous pursuit of science in Germany; but we may remark that it is certain that it is the distinct and emphatic belief of the most eminent scientific men of France: it is our clear duty, however, to inquire whether we are in a better condition in this matter than France was a year ago.

First. Are our men of science subordinated to place-seekers or politicians who, according to M. Deville, lack competence, and therefore the love of progress? It is a question even whether we have even reached this stage! In England there is absolutely no scientific organisation whatever, no minister whose duty it is to care one jot for science, no one man in office to whom either scientific instruction or the advancement of science is of the least interest—unless, perhaps, we except Mr. Lowe, and we all know in what point of view he from time to time turns from his more important avocations to deal with such questions.

So that on this point there is no comparison between the two countries. The French have an organisation, the working of which, according to their own showing, has been entrusted to incompetent politicians. We have no organisation whatever—which, perhaps, is a blessing, if we should be compelled to imitate the French plan—but we very often have to pay very dear for blessings, and this certainly is one which the sooner we get rid of the better.

Let us now pass from the disease to the remedy. M. Deville proposes that the French Academy should at once take up all large questions connected with the advancement and teaching of science (and we are glad to see that M. Deville does not put the cart before the horse, as is too much the fashion here) in order to liberate it from the political, administrative, and fiscal fetters which now paralyse it and to enable the country to make the most of every scientific idea or effort.

As we understand this proposal, M. Deville wishes that the Academy of Sciences should interest itself not only in abstract Science, and in the teaching of abstract Science, but in all the scientific inquiries or departments of all branches of the administration. To what extent interference is proposed in this latter case we have as yet no means of knowing, but it is easy to see that the further this goes the better it will be for the nation. Two matters which have recently occurred in England, to which we may refer parenthetically, will, we venture to think, strengthen our assertion. We shall not be contradicted when we state that if the Scientific Committee recently appointed by the Admiralty—a Committee which contains among its members Profs. Sir Wm. Thomson and Rankine—had been in existence when the *Captain* was built, instead of being appointed after that costly ship had simply turned bottom upwards because it was top heavy, we should now be the richer of a noble ship and five hundred men. And yet—and yet—we believe this Committee is only a temporary one. Take another case: A Commission was recently appointed to inquire into the Education of the Army. Was there a man of Science upon it? Certainly not. And what was one of the first things that came out of that Commission's report? This, namely, that most of the teachers of Science in the Army Schools received notice to quit. England, on the high authority of Lord Northbrook, did not want a Scientific Army.

All this by the way. We have referred to these instances, in order to show that the various departments of the Administration want scientific control here as is in France—that M. Deville's suggestion is of value here as there.

Now, assuming that the suggestion is a vital one, or even that it is an important one, and that it is good for England as for France, and we shall gladly open our columns to a discussion on these points; the question arises—is it possible to adopt it here?

We are met at once by the different conditions of the French Academy of Sciences, and our own Royal Society. The Academy is a large paid body; our Royal Society is a small unpaid body, and the work, which M. Deville considers so necessary for the regeneration of France, and which many consider necessary for the salvation of this country, is no temporary or small affair. The labour would be great, enormously great at first, and, moreover. would be a never ending one. To impose such a labour as this on a private body, which was constituted for entirely different purposes, would simply be to destroy that private body altogether, and it would be both unwise and unjust for such a body to undertake it, unless each member had ample means and no occupation. so that all his time and energy might be devoted to the task.

We think, then, that for these and for other reasons, not far to seek, it is impossible for our Royal Society to play permanently the *rôle* here which M. Deville has suggested to the Paris Academy.

But here, at length, is a grain of comfort. We have in England, at the present moment, a body at work, which if the general ideas of the power entrusted to it be correct, may perform those very services for England which M. Deville so loudly calls for—a call which all men of science *d'outre manche* re-echo—in the case of France. We refer to the Royal Commission on Scientific Instruction and the Advancement of Science, on which body, we take it, has devolved just such a general overhauling of all matters scientific within these realms as M. Deville has proposed—a herculean task, but a noble one if done well, and a task which will not be well done unless it is indicated how England can be put in a position second to no other nation so far as Science is concerned, a position that she certainly does not occupy at present.

But supposing all this done, we must have something more. We must have some permanent machinery, and having this we must have the scientific men mindful, above all other things, of the interests of science, and then our politicians will hear no uncertain sound as to the merits or demerits of State aid to the higher education. A nation, as a distinguished foreign *savan* has recently said, must endow science until that nation stands first (1) in abstract Science, (2) in the applications of Science generally, and (3) in the amount of knowledge possessed by State servants of all classes. When she has achieved this point the question of continuing State aid may properly be discussed—not till then. To this let us add that apart from the question of State-aided Science that nation will stand highest which, in addition to the above conditions, calls into her councils her men of Science, and becomes a Science-aided State. EDITOR

PANGENESIS

IN a paper, read March 30, 1871, before the Royal Society, and just published in the Proceedings, Mr. Galton gives the results of his interesting experiments on the inter-transfusion of the blood of distinct varieties of rabbits. These experiments were undertaken to test whether there was any truth in my provisional hypothesis of Pangenesis. Mr. Galton, in recapitulating "the cardinal points," says that the gemmules are supposed "to swarm in the blood." He enlarges on this head, and remarks, "Under Mr. Darwin's theory, the gemmules in each individual must, therefore, be looked upon as entozoa of his blood," &c. Now, in the chapter on Pangenesis in my "Variation of Animals and Plants under Domestication," I have not said one word about the blood, or about any fluid proper to any circulating system. It is, indeed, obvious that the presence of gemmules in the blood can form no necessary part of my hypothesis; for I refer in illustration of it to the lowest animals, such as the Protozoa, which do not possess blood or any vessels; and I refer to plants in which the fluid, when present in the vessels, cannot be considered as true blood. The fundamental laws of growth, reproduction, inheritance, &c., are so closely similar throughout the whole organic kingdom, that the means by which the gemmules (assuming for the moment their existence) are diffused through the body, would probably be the same in all beings; therefore the means can hardly be diffusion through the blood. Nevertheless, when I first heard of Mr. Galton's experiments, I did not sufficiently reflect on the subject, and saw not the difficulty of believing in the presence of gemmules in the blood. I have said (Variation, &c., vol. ii., p. 379) that "the gemmules in each organism must be thoroughly diffused; nor does this seem improbable, considering their minuteness, and the steady circulation of fluids throughout the body." But when I used these latter words and other similar ones, I presume that I was thinking of the diffusion of the gemmules through the tissues, or from cell to cell, independently of the presence of vessels,—as in the remarkable experiments by Dr. Bence Jones, in which chemical elements absorbed by the stomach were detected in the course of some minutes in the crystalline lens of the eye; or again as in the repeated loss of colour and its recovery after a few days by the hair, in the singular case of a neuralgic lady recorded by Mr. Paget. Nor can it be objected that the gemmules could not pass through tissues or cell-walls, for the contents of each pollen-grain have to pass through the coats, both of the pollen-tube and embryonic sack. I may add, with respect to the passage of fluids through membrane, that they pass from cell to cell in the absorbing hairs of the roots of living plants at a rate, as I have myself observed under the microscope, which is truly surprising.

When, therefore, Mr. Galton concludes from the fact that rabbits of one variety, with a large proportion of the blood of another variety in their veins, do not produce mongrelised offspring, that the hypothesis of Pangenesis is false, it seems to me that his conclusion is a little hasty. His words are, "I have now made experiments of transfusion and cross circulation on a large scale in rabbits, and have arrived at definite results, negativing, in my opinion, beyond all doubt the truth of the doctrine of Pangenesis." If Mr. Galton could have proved that the reproductive elements were contained in the blood of the higher animals, and were merely separated or collected by the reproductive glands, he would have made a most important physiological discovery. As it is, I think every one will admit that his experiments are extremely curious, and that he deserves the highest credit for his ingenuity and perseverance. But it does not appear to me that Pangenesis has, as yet, received its death blow; though, from presenting so many vulnerable points, its life is always in jeopardy; and this is my excuse for having said a few words in its defence. CHARLES DARWIN

THE NEW HOSPITAL OF ST. THOMAS

II.

THE large wards of the Hospital contained in the several flats of the Blocks 2, 3, 4, 6, and 7 * are rooms of noble dimensions. In the second, third, and fourth floors, each ward is more than 100ft. long, 38ft. wide, and 15ft. high; and as this space is designed for the accommodation of twenty-eight patients, each patient will have more than 2,000 cubic feet of air to his own share, irrespective of change by ventilation. But the arrangements for warming and ventilation are also very complete and admirable. The entire building is, in the first instance, warmed to a certain extent by pipes which receive supplies of hot water from large boilers fixed in the basements of each block of building. These heating pipes are expanded into broad radiating coils here and there where immediate increase of warmth is desired. There are two of these radiating coils to each ward. But in addition to these, there are also in each three *open fire-places* situated in the central line of the floor, and sending circular iron chimneys or flues up through the ceiling. These columnar iron chimneys are, however, double. Each has an inner central pipe, and an outer investing sheath. The inner pipe carries up the smoke of the burning fuel; the outer case collects all the effete and used-up air of the chamber, and discharges it with the smoke at the outer orifice above the roof, the central heated pipe being an efficient cause of a steady up-cast. The final outflow of both smoke and impure air is by the square turrets, which are seen from the outside as a part of the ornamental finish of the roof. The fresh air is brought from the outer wall beneath the floors, and is discharged into the wards *through the heated casings* of the fire stoves and radiating coils. This double plan of warming, partly by radiating hot pipes, and partly by open fire places, is the very perfection of efficiency and comfort. Private residences in England are almost always uncomfortable in very cold weather, however liberal may be the consumption of fuel, because the larger and brisker the fires, the more intolerable are the indrafts of cold air. The cylindrical smoke pipes run straight up from basement to roof through the entire series of floors, so that when the flues require cleansing, a kind of plug is removed from the bottom of the pipe, and the entire accumulation of soot is brought down at once into one of the cellars of the basement, without causing any interference with the comfort or cleanliness of the several wards above.

There are nurses' chambers on either side of the entrance of each large ward; and at each side of the farther end corresponding turrets, or corner rooms, containing lavatories and baths on one side, and closets on the other with convenient little shoots, which are to convey the dust of sweepings and the soiled linen of the patients down at once to the offices in the basements. Near the nurses' chambers there is also a large square lift, worked by hydraulic power, to be used in conveying patients and supplies of all kinds, up and down between the projecting corners, or turrets (at *b b* on the plan). At the further extremity there is a most delicious open-air balcony looking over the cheerful river, with ready access to it from the windows of the wards.

Block No. 9, being designed for the reception of infectious and contagious diseases, is differently planned. There are smaller wards on each side opening from a central stair-case and landing. Between the Blocks 2, 3, and 4, and between 6, 7, and 8 (at *a*, *a*, on the plan) are low buildings rising in broken and ornamental form from the general line of the connecting corridor, which will be used for the residence of officers of the establishment. Connected with the upper part of these, there is a fine surgeons' operating theatre at each side of the building, one for males and the other for females. These are entered from the light and airy glazed corridor of the second floor, and have retiring-rooms for patient and surgeon, and a direct way to a pleasant open-air flat roof looking out over the river.

In communication with the great connecting corridor there is a perfect maze of offices and conveniences, approached by an accident-receiving porch abutting on the Lambeth Road. There are receiving-rooms for out-patients and for surgical cases and accidents, dispensaries, and a long range of small private rooms for the medical and surgical officers, clerks, and dressers. The Administrative Block, No. 1, is entered from the Westminster Bridge Road by two flights of steps, one leading to the private residence of the Treasurer of the Hospital, and the other to a large Council hall looking out by a balcony upon the river, and to Committee rooms and other offices, which are to be connected with the other departments of the establishment by lines of electric telegraph. The general entrance of the Hospital is from the Lambeth Road, leading to a spacious hall in the central block, No. 5, above which is the Chapel of the Hospital, a vaulted building of fine proportions and very chaste design. This block will be finished towards the river front, where it is set back or recessed from the line of the other blocks, by an ornamented face which looks out on an enclosed space or central court. From this court the prospect to the river is between the pillars of an open colonnade, bearing in the centre a group of sculptured figures, of which the chief will be the statue of Edward the Sixth, the royal founder of the Hospital.

Block No. 9 has much more the appearance of a church, or chapel, than the central building. It is of low elevation, compared with the other blocks, and has ornamental arched windows of large size; and at the corner there is a square tower, half steeple, half pagoda, which

* See plan in NATURE No. 63, p. 202.

is altogether suggestive of a campanile. It is only when the eye is carried along the general range of the buildings, and it is noted that this tower is simply the architect's contrivance for raising the chimney turret in the case of this lower erection to the same height as the chimney turrets of similar aspect on the higher blocks, that the idea dawns upon the observer that this building may have a very different purpose to perform than affording accommodation for religious worship and service. It is, indeed, a temple for the dead rather than for the living. It is properly the Museum and Medical Schools of the Hospital; and the lofty tower will be employed to waft the vapours of effete corporeal mortality well up into the purifying atmosphere. Its interior will be warmed by hot-water warmed air to feed the combustion of the open fires. This evil is entirely obviated by this plan of having half pipes and radiating coils, to cause a strong up-cast; and will gather the air from brick channels of escape which permeate all portions of the building. The most surprising thing about this terminal block of the Hospital is the vast amount of accommodation that has been got out of it by dint of good package and clever arrangement. It looks like a tolerable-sized chapel, and might really be no more, yet it really contains a very capacious Museum, four large Lecture Theatres, a Chemical Laboratory, a Dissecting-room, mortuary chambers, and students' halls. It is, in fact, one of the most commodious and best ordered Medical Schools in the Metropolis.

There is a long tunnelled way under ground, running to the chambers for the dead in this building, from the several Hospital blocks, from one part of which a branch passage leads to the wash-house and laundry. One of the mortuary rooms is to be arranged as a sort of Morgue, or reception room for friends who come to pay a last visit to the dead; and a pair of large gates opening upon the Lambeth Road will admit the hearse to this portion of the Hospital, when it comes to claim those portions of the remnants of vitality that have not found another mode of escape through the campanile tower. This "old mortality" end of the Hospital nestles curiously close under spiritual over-shadowing. It is only separated from the battlements of the Archbishop's palace at Lambeth by the stables and coach-house of the Treasurer of the Hospital.

The new Hospital of St. Thomas promises to be one of the most complete and efficient of the hospitals and medical schools of the metropolis. R. J. M.

ZOOLOGICAL TEXT-BOOKS

General Outline of the Organisation of the Animal Kingdom and Manual of Comparative Anatomy. By Prof. Rymer Jones, F.R.S. (Van Voorst.) Fourth Edition. 1871.

A Manual of Zoology for Students. By Dr. Henry Alleyne Nicholson. (W. Blackwood and Sons) 1870.

THE mass of information which is continually and rapidly accumulating in every department of Natural Science, renders it increasingly desirable that every manual writer should zealously aim at combining terseness with accuracy, and, by a well-chosen selection of the most important facts, exhibit the results of the more recent acquisitions of science. In the ponderous volume of 886 pages, which now replaces the long-known "Comparative Anatomy" of Prof. Rymer Jones, the very opposite characters are painfully conspicuous, and we sincerely pity the student who has recourse to it for his instruction in zootomy. Not but what the book is both highly instructive and interesting, and exhibits conspicuously the learning, patience, and zeal of its accomplished author. For all this, however, the youth who gets up his zoology and comparative anatomy from it, will find himself out of joint with and wanting, as regards the zootomy of the present day, while he will have wasted time over comparatively useless and antiquated details.

The Rotifera are, indeed, strangely located, being described in one chapter with all the Crustacea except the Cirripeds, which latter are placed apart in a separate chapter. A still more important defect, however, and one almost incredible, is the complete omission of all reference to the Rhizocephala. After this it is not surprising that no notice is taken of those recent discoveries as to larval Ascidians, which seem to indicate a genetic affinity between them and the Vertebrata, and which are now made familiar to all by Mr. Darwin's "Descent of Man." This is the more remarkable, as at p. 666 the author speaks of the Amphioxus as in some respects resembling Ascidians, and being thus connected with the Mollusca. Another singular and conspicuous blot is the location of the Brachiopoda between the Lamellibranchiata and the Gasteropoda.

When we come to the great Vertebrate division of the animal kingdom, we are again painfully impressed by defects and shortcomings, which sometimes must lead to downright error on the part of the unlearned reader.

The Batrachians are lumped together with the true Reptiles in one class, and the student could hardly gather from Prof. Rymer Jones's pages that the true affinities of the former are with fishes, while the latter are closely related to birds. In the general index we read "Comparison between Birds and Reptiles, p. 760, sec. 2,032." We turn to the page and section indicated, expecting to find a succinct statement of the results arrived at by Profs. Huxley and Cope. In reality we find but a meagre statement of the obvious physiological contrasts between the two classes.

Owen's hypotheses as to the essential nature of the vertebrate endoskeleton and its several parts, are given without criticism or discrimination, as if they were views universally received and recognised. But there are positive errors which it is difficult to stigmatise too strongly. Thus, in spite of Prof. Huxley's papers, it is gravely asserted of the terminal caudal vertebræ of homocercal fishes, that they "are commonly blended together, and shortened by absorption, whilst both neural and hæmal arches remain with increased vertical extent, and indicate the number of the metamorphosed and obliterated centrums!"

Of Prof. Owen's hæmal cranial arches, it is said that his labours "have satisfactorily revealed their real nature, and established *beyond a doubt* (the italics are ours) the alliances which exist between the elaborate structures in question and the arches which exist under singular conditions appended to the vertebral segments of the trunk."

At the other end of the skeleton all the valuable researches of Mr. Parker, Prof. Huxley, and antecedent Continental authors are ignored, and the essential affinity between the embryonic mammalian skull and its permanent condition in Batrachians and cartilaginous fishes is passed over in silence.

Similar incompleteness is to be found in treating of single organs in single classes. Thus, in speaking of the swimming bladder, its homology with the lung is only faintly alluded to in terms hardly of approval, and nothing is said of its interesting condition in Polypterus.

As to Birds, the inquirer who consults this manual only will fail to acquire any really adequate knowledge of the class, from the absence of all description of its two very distinct existing types—the struthious and the carinate birds. As regards the omission of any notice of the Archæopteryx, it may be pleaded that it is a fossil form; still a manual of zoology must be reckoned as singularly incomplete which fails to call attention to a form so importantly aberrant.

In the highest class of Vertebrates we miss any adequate statement of the very great gap which exists between the Monotremes and the higher Mammals.

Prof. Flower's careful labours regarding the corpus callosum are utterly ignored. Thus we read, "In those Marsupial tribes that form the connecting links between the oviparous and placental Vertebrata, the brain still exhibits a conformation nearly allied to that of the bird, and the great commissures required in the more perfect encephalon are even yet deficient; but in the simplest brain of a Placental Mammifer the characteristic differences are at once apparent." The student is left entirely in the dark as regards the large anterior commissure of the lower forms which compensates, as it were, for the reduction of the corpus callosum, while presenting such a contrast to the brains of birds and reptiles.

The facts here mentioned will enable the zootomically instructed reader to appreciate the defects which unhappily characterise this last production of Prof. Rymer Jones. As we have said, they do not prevent the volume being replete with both interest and instruction, and a large number of readers may study it with advantage, though it is not calculated for young students who wish to be *au courant* with the latest views and those received by the most esteemed biologists. The prevailing character of the book may be summed up by saying that we have in it almost a maximum of physiological anatomy with a minimum of morphology.

Turning to the much smaller work of Dr. Nicholson, we feel refreshed by coming in contact with a body of more modern views and less-known facts put forth concisely and in a form really useful to the student. There is a copious glossary, the utility of which will far more than compensate for some inaccuracies. There is also (what no book of the kind should lack) an alphabetical index, the want of which will be sadly felt by those who use Prof. Rymer Jones's volume. Nevertheless, Dr. Nicholson's manual, though serving as a stop gap to supply an urgent need, is not, by any means, all that could be desired. Some of the very glaring omissions we have noticed in the large work are also defects in the smaller one. Thus we have again the absence of any reference to the Rhizocephala, but that larval Ascidian structure is noticed "which has been paralleled with the chorda dorsalis of Vertebrates."

The Brachiopoda are relegated to the vicinity of the Polyzoa, and removed from the Mollusca proper. The Batrachia are associated with the fishes, the Reptila with the Birds. Man is put back into the order Bimana, which appears to us a mistake when he is considered from the zoological point of view only. Investigations and discussions of recent date have abundantly demonstrated that in bodily structure he differs far less from the higher "so-called" Quadrumana than do these latter from the lowest members of that order. In connection with recent investigations it must be remarked that Dr. Nicholson does not sufficiently acknowledge how largely his work reposes on the labours and teachings of Prof. Huxley. That Professor's system and arrangements are almost entirely adopted, even to the location of the class Echinodermata in the subkingdom Annuloida.

It is much to be regretted that the last-named eminent naturalist has not ere this given to the world the results of his labours in his own clear and terse language, and published a model handbook for the use of students. In the absence of such a desideratum we feel sure that Dr. Nicholson's work will, for a time, be deservedly popular and widely used. More than this we cannot, however, anticipate for it without careful and copious additions and emendations.

OUR BOOK SHELF

A History of the Birds of Europe, including all the Species inhabiting the Western Palæarctic Region. By R. B. Sharpe, F.L.S., &c., and H. E. Dresser, F.Z.S., &c. Part I. (London: published by the Authors.)

THIS work will supply a great want, since it will give in a convenient form and at a moderate price, a really good coloured figure with a full and accurate description and history of every European bird. The talent of Mr. Sharpe for publications of this nature has been sufficiently shown by his beautiful work on the kingfishers, which we have already noticed, while his colleague, Mr. Dresser, is an enthusiastic student of European birds. In M. Keulemans they have secured an artist who bids fair to rival Wolf in the delineation of bird character; and if the work maintains the standard of its first part (and we have every reason to believe it will do so), its subscribers will have cause to be satisfied. We find in the part now issued eight species of birds beautifully figured, and about forty-six pages of letterpress, crowded with information from every available source on the habits and distribution of the species. The series of charming pictures of the most graceful of all living things which this work will give, must render it a general favourite; and it will assuredly help to extend the growing taste for natural history, by rendering it comparatively easy for the traveller or resident on the Continent to determine the species and refer to an outline of what is known about any bird he may meet with during his rambles in the country or in the markets. To the home naturalist, also, it will prove far more interesting than a work on British birds alone; for he will here find how far over the globe his feathered friends are accustomed to range, and will make the acquaintance of many members of their several families who, although they live permanently abroad, yet retain a strong likeness to their English relations. We heartily wish Messrs. Sharpe and Dresser success in their bold and laborious undertaking.

A. R. W.

A Treatise on the Action of Vis Inertiæ in the Ocean. By W. Leighton Jerdan, F.R.G.S. (London: Longmans.)

THIS book is a lamentable instance of misconception and error. It is founded on a denial of the first law of motion that a body, if moving, will continue to move in a straight line with uniform velocity, provided no forces act on it. There is through the whole book the most hopeless confusion as to what is meant by no forces acting. The author's theory of the cause of the moon's motion will illustrate the character of the book. It is briefly this:—If the moon were pulled only by the earth's gravitation, it must fall to the earth. It must therefore be pulled in the opposite direction with an exactly equal force. This is called by the author the force of astral gravitation. Since these two exactly balance one another, the question arises, What can cause the moon to revolve round the earth? "A cause," says the author, "for the onward motion of the moon according to the action of well-known laws, is, however, indicated by various well-known tidal phenomena. For the moon tends to raise a mass of water or tide on the earth's surface beneath it; and as the earth's surface rotates eastward, it tends to carry that mass of water or tide with it; and therefore as the moon tends to hold the tide beneath it, the rotation of the earth eastwards must just as certainly tend to carry the moon eastwards as to carry the tide eastwards." Really it is quite irritating that such nonsense should be printed in large type, on good paper, and in a well-bound book.

It is one of the great merits of error that it is inconsistent. That the author enjoys the full satisfaction of this merit is evident from the following:—"If the moon and earth were at rest, then astral gravitation would tend to carry the moon directly from the earth, not at a tangent to any part of its orbit; and when in motion, astral gravitation tends to carry the moon off at a tangent from its orbit certainly, but *in the opposite direction to that of its motion* at the moment of its being released from the grasp of the centripetal force." The italics are the author's—not ours. It appears from this that the author denies the second law of motion, as well as the first, which he elsewhere denies. He here assumes that the effect of a force on a body at rest can be at right angles to its effect on that body when in motion. It is much to be desired that those who undertake to write books would first learn the first principles of that which they write about.

Catalogo Poliglotto delle Piante. Compilato dalla Contessa di San Giorgio. 8vo., pp. i., 747. (Firenze, 1870.)

We wish to call our readers' attention to this interesting little volume. Its authoress will be better known in the country as Lady Harly of Oxford; and she has spent many years in the compilation of this volume, which, we think, may prove useful to travellers on the Continent, and indeed, might even be made the means of instruction in our public schools. As an example, we select the *Bellis perennis*, which, a native of Europe, we find is, in English Daisy; French, Paquerette, *Marguerite vivace*, Fleur de Pâques; Italian, Pratolina, Margheritina de Prati; Spanish, Maya, la Margarita; German, Masslieben, Gänse Blümchen, Angerblume, Osterblümchen. But we find not only the European names of a large number of plants given, but, even in some instances, the Sanskrit, Bengal, Hind and Tamul names are also appended.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Variability and Natural Selection

I ask your permission to address to your readers some observations in support of the argument which Mr. St. George Mivart has adduced in his work on "The Genesis of Species," that Mr. Darwin has attributed too exclusive an effect in the origination of new species to the influence of his law of Natural Selection.

1. There are two facts on which Mr. Darwin's theory reposes—the one the variability of animal and vegetable forms; the other, the accumulation of a useful variation by force of the struggle for existence, or Natural Selection. Mr. Darwin assumes Variability to be accidental, not because he or any other philosopher supposes that there is such a thing as accident, but because its law is unknown. He then finds the law of Natural Selection, and by this and this alone, explains the Genesis of Species.

Now, inasmuch as Natural Selection operates on Variability as a pre-existing fact, it follows that the genesis of a new species must result from the operation of two laws—namely, the law of Variability and the law of Natural Selection. But Mr. Darwin attributes it exclusively to the latter; so that, according to his view, there is a law (that of variability) which has no part in producing a result which yet depends for its existence on the fact regulated by that law—namely, variation. This is enormously improbable. It is as if the resultant from two factors were attributed exclusively to one of these factors.

The fact that Mr. Darwin assumes variation to be accidental is, of itself, sufficient to make us expect some residual phenomenon not accounted for by the law of selection: but Mr Darwin's argument does not allow the existence of such a residuum.

2. Mr. Mivart, following the *North British Review*, has shown the great advantage in the struggle for existence which the numerical superiority in individuals of the original form over the new variation may give to the original form. I want to call your attention to the fact, that the useful variety has to overcome not only this advantage to its antagonist resulting from numbers, but a quite distinct difficulty, namely, the tendency to reversion; or, that in other words, the force which Mr. Darwin has at his disposal is not the tendency to accumulate a variation, but only the balance of this tendency over the tendency to reversion.

It is no doubt difficult to estimate the extent to which one tendency is controlled by the other; but to gain some notion of it, let me assume the existence of three forms, with a male and female of each, viz.,

male	female
a	a' the original form
b	b' the first variety
c	c' the second variety

Let me further indicate the existence of an accumulated variation by the double letter *bb*, or *cc*. Let me then assume an equal chance of sexual intercourse between each of the six individuals and of progeny from such intercourse, and we shall see what are the chances of the origin of an accumulated form. For the union of

a	and	a'	produces	a
a	,,	b'	,,	a
a	,,	c'	,,	a
b	,,	a'	,,	a
b	,,	b'	,,	bb
b	,,	c'	,,	a
c	,,	a'	,,	a
c	,,	b'	,,	a
c	,,	c'	,,	cc

So that in the first generation the chance against any given accumulated variation being produced are 8 to 1, and the chances against any accumulated variety at all being produced are 7 to 1; and these odds will go on increasing, because the next generation will retain the tendency to revert to the original simple parent form *a*, not to the original forms of the last preceding generation only. If I assume that each marriage in the first generation produced two males and two females, the result will be, that in the second generation the chance against any given accumulated variety being produced will be 320 to 4 or 160 to 2; and the chance against any accumulated variety at all being produced will be 316 to 8 or 79 to 2.

These chances express the force of the tendency against which Natural Selection has to operate, assuming that the numbers of each variation at starting were equal to those of the original form; but this is, on the assumption that variation is accidental, infinitely removed from the truth; and if the difference between the numbers of the original form and the variation be introduced into the case, the odds are indefinitely increased against the accumulation of a casual variety. None of these observations goes to show that Natural Selection does not exist (I have no doubt that it does), but they show that it has a most uphill game to play, and one in which it is improbable for it to win without help from some other principle.

It may be objected to what I have alleged that the result of the marriages between the individuals of the original form *a* and the varieties *b* and *c*, will not be of the pure original form, but forms half way between that original form and the variety. This will often be the case, but then the improper form of *a* will have in future generations an increasing tendency to revert to the pure original.

3. Mr. Mivart has adduced the co-existence of closely similar structures of diverse origin as evidence that there is a law of Variability over and above the principle of Natural Selection.

The argument appears to me worthy of great consideration. If variability be a force operating in every direction equally, it is very improbable that the course of any two variations should run parellel; if on the other hand the tendency to variation operates along particular lines, then it is likely that the lines which represent the course of separate varieties should run parallel. How do the facts stand? The placental and marsupial quadrupeds form two distinct groups which branched off from one another in very remote times, and yet the two groups have developed into classes and sub-groups so correspondent that their courses may best be described as two parallel zigzag lines. Such a fact almost necessarily involves the conception of one and the same force controlling each group, so as to make it pass along its respective course, just as the likeness of two oak trees implies a like inherent force in each acorn.

But this is not the only instance which Mr. Mivart adduces; he produces the fact that there are two parallel bridges which span the space between birds and reptiles; and I desire to add this further fact not noticed by Mr. Mivart, that there are in like manner two parallel bridges between fishes and reptiles. As is well known, there still exists a small class of animals, half fish and half reptile, often known as the Amphibia. They possess lungs like reptiles, but like fish they have gills and the consequent modification of the hyoidal arch, and their fore limbs have what may be called a degraded and fishlike form. The Archegosauri are extinct creatures of the carboniferous strata—like the existing Amphibia, half reptiles, half fish; like them they carried both gills and lungs, and like them they had the fore limbs in a degraded condition. So far there is nothing to the point; but to the foregoing must be added that the existing Amphibians are a bridge between reptiles and the hard-boned fishes, which are the predominant modern class; whereas the Archegosauri were a bridge between reptiles and the ganoid fishes, to which class they were related by the character of their teeth, the imperfect ossification of the internal skeleton, and the excess of ossification in the external skeleton (Owen's Palæontology, p. 193, *et seq.*). This observation will remain true, even if it should be shown, as some naturalists expect, that the Archegosauri were a tadpole form of a more perfect reptile; for it can hardly be doubted that the immature form expresses the history of the perfect one, and shows by its likeness to the ganoid fishes the original relation to that class.

It has often appeared to me, that there are striking parallelisms in the three great groups of the Quadrumana. For instance, the vocal organs of the Hylobates or Gibbons of the Indian Archipelago present a close relationship to those of the Mycetes or Howlers of the South American forests. The nocturnal and insectivorous habits of some of the American genera recall the like habits of most of the Lemurs: and again, the Baboons are related to the Anthropoid Apes in a way which suggests to the mind that the similarity of their forms is greater than the nearness of their kinship.

There is no doubt that similar parallelisms may be observed in very many groups; and I think that many of those phenomena of likeness which Mr. Darwin would attribute to atavism may as well be explained by the retention in each group of the force which was inherent in the original family from which both groups have proceeded.

This sort of parallelism is well illustrated by a very common accident: a tire gets loose from a wheel; but both it and the wheel pursue nearly parallel courses, except so far as they are operated upon by different external forces.

EDWARD FRY

Protective Resemblances

HAVING read the various papers by Messrs. Bennett, Murray, Wallace, &c., in NATURE, and thinking that my observations made on plants and animals in various parts of Southern Africa may be of some interest to your readers, I am rather hastily putting together a few facts, which it had been my intention to have worked up into an illustrated paper, but which may perhaps prove of most interest at present, while the discussion is still warm.

I must own that I prefer the use of the general term "protective resemblance" to the special term "mimicry," as the latter seems to imply a certain amount of *intelligent volition*, which in the instances cited by Messrs. Wallace, Bates, and Trimen, I believe does not apply, whereas there are, I believe, cases where instinct does come into play, not acting physiologically as Mr. Bennett would seem to assert, but in the construction of disguises.

Mr. Bennett's argument appears to me as fully adverse to his own theory as to Mr. Bates's, and if Mr. Murray's theory is correct then it ought equally to apply to animals so widely different as ants and spiders.

Protective resemblances appear to me to be capable of being roughly classed as general and special, though both run into each other. Of general resemblances there are so many that I hardly think it worth while to enumerate instances, I shall therefore confine myself to some examples of special protective resemblances which I have noted.

1. As to plants I believe protective or useful resemblances are far commoner than some writers seem to think.

That excellent observer Dr. Burchell, in his "Travels," vol. i., p. 10, remarks:—"On picking up from the stony ground what was supposed a curiously shaped pebble, it proved to be a plant, and an additional new species to the tribe of Mesembryanthemum, but in colour and appearance bore the closest resemblance to the stones between which it was growing. On the same ground was found a species of the Gryllus tribe amongst the stones, and so exactly like them in colour and *even in shape* that it could never have been discovered had it not been observed just at a moment when in motion, and as if more completely to elude notice it seldom stirred, and even then but slowly.

"The intention of nature in these instances seems to have been the same as when she gave to the chameleon the power of accommodating its colour in a certain degree to that of the object nearest it in order to compensate for the deficiency of its locomotive powers. By their form and colour, this insect may pass unobserved by those birds, which otherwise would soon extirpate a species so little able to elude its pursuers, and this juicy little Mesembryanthenum may generally escape the notice of cattle and wild animals."

I may here remark that a great number of Karoo plants have tuberous roots of similar form and colour, and it is especially curious to notice that, amongst the Asclepiadeæ, many species, such as *Raphionueme*, which are found in the grassy country, have their tubers hidden beneath the soil, whilst others, which occur in the stony Karoo, such as, *Brachystelma filiforme*, have them above the soil, and so perfectly do they resemble the stones amongst which they are found, that, when not in leaf, it is almost impossible to distinguish them.

Of imitating plants I may mention *Ajuga ophrydis*, the only species of the genus in South Africa, which bears a striking resemblance to an orchid, as also does *Impatiens capensis*, another solitary species. I mention these especially because they are very striking, although I am not aware that they are in any way specially useful, noting, however, that the latter plant is much frequented by insects, often by similar species to those which frequent *Angræcum* and *Mystacidium*, plants affecting similar localities.

I know of many similar resemblances between plants belonging to most different orders, but cannot say how far they are merely fortuitous, and I am anxious to avoid Mr. Bennett's reproach of being "ultra-Darwinian."

With respect to the orthopterous insect mentioned by Burchell, that excellent observer, Mrs. Barber of Highlands near Grahamstown, communicated a most interesting paper to the Albany Natural History Society on a "Stone Grasshopper," which varies according to the nature of the soil of the district it inhabits; and I have in my collection numerous species of Locustidæ collected in the Karoo, whose successful imitation to the soil is most remarkable. I may remark here, that many most singular species of insects lose half their interest when penned down in a collector's cabinet.

As mimicry amongst mammals and reptiles is noted as rare, I may mention instances of what appear to me to be cases.

The plains of S. Africa are characterised by numerous animals generally known to the Boers as "Mierkatjes" (not little monkeys as Burchell renders it, but literally "ant cats"). Most of these are Viverrine Herpestes, Suricates, &c., and all have nearly similar habits. Early in the morning these pretty animals may be seen in numerous groups sitting up on their hind legs warming themselves in the sun, and, when startled, scampering away to their holes, with their tails cocked high up in the air. They are likewise more or less coloured like the Karoo soil, although when individually examined their colours, of course, differ.

All these feed on mice, small reptiles, and grasshoppers and locusts. They likewise greedily devour birds' eggs. Equally common with these in some parts, but especially noticed by me near Cradock, is the *Xerus setosus* Gray, or ground squirrel. It is likewise known as a Mierkatje by the Boers. Unlike the other Mierkatjes it feeds on small bulbs and tubers called "limtjes" by the Boers. Its colour, habits, and long tail, cocked up in the air, gives it a striking resemblance to its Viverrine neighbours; while in common with them it forms burrows in the ground. Of reptiles there is a species of *Dasypeltis*, a snake almost devoid of teeth, very common about Algoa Bay, but with whose specific name I am not acquainted. When irritated this species coils itself up and darts angrily at the intruder, puffing and hissing loudly. When I first met with it I was rather cautious in handling it; but discovering its harmlessness I have kept several in confinement.

A few years ago I was examining some Bushman caves in the Nuncazana Valley, Bedford District, when my Hottentot servant told me that there was a "Groste Nacht-adder" in the cave, and I found what I also took to be a large Night adder. It sprang at us, and nearly escaped. On examining it when dead I was much surprised to find it was a very fine specimen of my old friend the *Dasypeltis*, as I had not met with the species since I had left Port Elizabeth. Night adders are common in the Nuncazana, as also here. On comparing the two snakes I was much struck by their general resemblance, although, of course, the *Dasypeltis* has a very dissimilar head; but the curious way it has of blowing itself out, and distending its neck, and darting at intruders, heightened the resemblance. I cannot help thinking that these habits must be serviceable to so harmless a snake.

In general protective resemblance Reptiles and Batrachians offer countless examples, and it is especially noticeable amongst the *Agamidæ*, one species of which varies throughout the eastern part of the colony and Free State.

With respect to butterflies I need not enlarge, Mr. Trimen having done his work most thoroughly. I may mention, generally, that *Philognoma varanes*, when its wings are closed, strikingly resembles a dead leaf, and two of its varieties, ♂ and ♀ *P. Agathina*, are found in forests, and their flight strongly resembles falling leaves, as does also that of *P. poppea*. In his work on the "Rhopalocera" he mentions the resemblance between the larva of *Diadema bolina* and *Danais chrysippus*. Amongst birds which I have noticed capturing Lepidoptera I may mention that I have seen *Tchitrea cristata* darting at *P. Agathina; Cypselus caffer* I have seen take small moths from the grass, and dart at *Terias Rahel* on our open flats; *Motacilla capensis* I have seen take moths and *P. hellica; Dicrurus musicus* is a voracious bird amongst insects, and takes moths, though I cannot state I have seen it capture Rhopalocera, yet I think it also attacks *Pieridæ*.

Mantidæ and some species of flies are, together with spiders, I believe, the greatest persecutors of Rhopalocera. One large kind of fly pursues *Satyridæ* and *Tulbaghia meneris*. I have found a Phasma in the crop of *Strix affinis*.

The most perfect cases of mimicry I know of are two spiders (specific nature unknown to me) which bear the closest resemblance to ants. They belong to the *Salticidæ*, and are, apparently, related to *Salticus formicarius*. The one is smooth, black, and shining, and runs rapidly on the ground and bark of trees, and resembles the ant which builds its nest in *Acacia horrida*, and is used by the Kafirs for the purposes of torture. The other is larger and has its cephalothorax dull black, and its abdomen covered with short yellowish hairs. It is generally found running on the stems of herbaceous plants and small bushes, and closely resembles an ant found in similar situations. The fore legs in both species are larger than the second pair, and are frequently held up, when they closely resemble the antennæ of ants. So exceedingly close is the resemblance that, at first sight, I have almost always taken them for the imitated ants.

The most singular cases of protective resemblances in other orders are those of *Pephricus paradoxus* Sparr.; particularly remarked on in that traveller's work on South Africa; of another Heteropter in my possession apparently allied to the genus *Phlœa*, and which I discovered by the greatest fluke, so closely did it resemble a knot of the twig on which it was; of two species of Phasma, one believed by Mr. Trimen to be *Palophus Haworthii*, Gray, both of which were found in the Karoo on dead branches. *Acacia horrida*, known as the "Doorn Boom," or Mimosa throughout the Eastern province, is a perfect museum of protective resemblances.

I have the larva of a moth, which forms a case so exactly like the thorns of that tree that no one could detect it when not in motion; Mr. Trimen will, I hope, determine the species. A caterpillar belonging to a geometric moth, which piles the blossoms on its back, and doubles itself up so as exactly to resemble the flower heads; a larva of a species of *Neæra*, which exactly resembles the young thorn leaves on which it feeds, and which forms a pupa in a case resembling an excrescence of the bark; an Epeira which has two excrescences on its abdomen exactly resembling two old broken thorns. I could recount a number of other similar instances, but for the fear of trespassing too much on your space.

Lastly, I would remark how long it often is before frugivorous birds discover fruit not indigenous to the country.

In the drought of 1865 I was much struck by this. We had a solitary damson tree, which had not previously borne much fruit, but which that year had abundance. The mousebirds (*Coleus*) and the Red-wing (*Inida morio*) had devoured the almond and peach blossoms and the figs. With two double-barrelled guns we could not keep them from the latter. Meanwhile the damson tree was never touched, but ripened its fruit beautifully. On the morning of Christmas Day my friend intended taking them to his sister-in-law. Two hours later there was not a damson on the tree; the birds had just found them out, and had strewn the ground with their stones.

Now it has struck me that slight variations in insects may be of much greater value than one might at first sight imagine, and such would Mr. Weir's experiments lead one to expect, the birds selecting certain kinds of dull coloured larvæ from amongst others.

The beautiful instances afforded by the plants and insects I have enumerated can surely be only interpreted by Natural Selection. There can be no hybridism nor instinctive accumulation of resemblances in plants or between plants, grasshoppers and stones, and why should we go out of the way to call in a theory or theories, for which there are no facts as supporters, when we have at hand an explanation so much simpler, and which readily embraces every case?

I have myself no doubt that instinct may come into play, as in the case of the thorn imitator, &c.; and I believe something of the kind is noticeable in savage man, in the disguises he uses. It is a well-known fact that our soldiers often fired at aloes in the Fish River bush, mistaking them for Kafirs, as their red paint is an excellent disguise in the Bush. The North American Indian and the Bushmen adopted numerous disguises in hunting their prey, or in tracking their enemy, and no one who has not seen the latter can appreciate his wonderful power of imitating all kinds of animals.

In conclusion, I may remark that whilst many species of Rhopalocera are most abundant in S. Africa, it is very rarely that one finds their larvæ or pupæ. I have been astonished at the small success I have had in cases where the imagines are most abundant. J. P. MANSEL WEALE

Sexual Selection

MR. DARWIN in his recent work on the "Descent of Man" has shown that throughout the animal kingdom the male generally displays the stronger passions and is always the most eager. The males, moreover, whenever secondary sexual characters occur, are, as a rule, the possessors of weapons for defence or offence, brilliant colours, or other ornamental appendages, all of which Mr. Darwin supposes to have been acquired through sexual selection, either for the purpose of charming the female or for struggling with other males for the possession of the females. In a few exceptional cases among birds, the females are the wooers, and these are then more brilliantly coloured than the males. In Westwood's work on insects* I met with the following passage:—"M. Donzel has published a curious memoir upon

* "An Introduction to the Modern Classification of Insects." Vol. ii. p. 336.

the flight of butterflies whilst coupling (Ann. Soc. Ent. de France, 1837, p. 77.) showing that whilst the males of *Pontia Brassicæ*, &c., *Colias*, and *Polyommatus* support the females, it is the latter which support their partners in the genera *Thais, Thecla, Argynnis, Melitæa, Hipparchia*, and *Pieris*." Now this is strictly analogous to these exceptional birds, because, among our British representatives of these genera whenever a considerable sexual difference of colour occurs, *the female is always the more brilliantly coloured.* Thus, the female *Thecla Quercus* has the bright purple patch, and the female *Thecla Betulæ* the brilliant orange blotch on the fore wing, while the females of *Hipparchia* (*Satyrus*), *Janira*, and *H. Semele* are considerably brighter than their partners. The female *H. Megæra* is rather brighter than the male, and the same is true of *Colias Edusa* and *C. Hyale*, since the females of these species have orange or yellow spots in the black marginal border, represented in the males by thin streaks only. The females of the whole genus *Pieris* also are ornamented with black spots on the fore wings, which are only partially present in the males. I must confess that I am not convinced of the action of sexual selection in producing the colours of insects, but it cannot be denied that these facts are strikingly corroborative of Mr. Darwin's views. With few exceptions the rule holds good throughout the exotic species of these genera.

R. MELDOLA

The Irish Fern in Cornwall

OWING to an accident I did not see NATURE for the 23rd of February till yesterday. In a note which appears in it, on the report of the Cheltenham College Natural History Society, a doubt is expressed as to the accuracy of the statement that the fern, *Trichomanes radicans*, has been found in Cornwall. Knowing that it had not yet been recorded from that county, I have, for some years past, intended to take an early opportunity to make the following facts public ; time has, however slipped away, and I have never yet done it.

In August of the year 1867, at St. Knighton's Kieve, a romantic ravine and waterfall on the northern coast of Cornwall, about two miles from Tintagel Castle, I obtained an undoubted specimen of this fern. It grew on a rock overhanging the water, about a quarter of a mile below the fall. It was an exceedingly small patch, and I accordingly contented myself with a small root bearing two fronds. Wishing to grow this specimen instead of drying it, and having unfortunately placed it in a hot-house, the plant died. I have, however, preserved it, withered and dried up as it is, and when I return to London, where my herbarium is, I shall be glad to produce it for the satisfaction of any sceptics. In the following year (1868) I paid an exceedingly hurried visit to the same spot, but failed to find the fern ; never having been in the neighbourhood since, I have been unable to confirm or to dispel my fear that the plant has been discovered by some ruthless collector. I may add that I have long since mentioned this fact to various friends interested in Botany.

Morebattle, Kelso, April 6 EVERARD F. IM THURN

Fertilisaton of Hazel

IN a recent number of NATURE Mr. Bennett makes some remarks on the above. What he says leads to the belief that the male flowers of any one plant discharge their pollen just at the very time the stigmas of the female flowers of the same plant are receptive. My observations made this spring, and extending over a number of specimens, quite agree with those of Mr. Marcus Hartog, and therefore break through Mr. Bennett's law, and show that although the hazel is apparently monœcious, yet, practically, it is diœcious. On one plant which I pointed out to several gentlemen, the fertile flowers had their pretty red styles protruded beyond the scales and the receptive stigmas long before. a grain of pollen was discharged from the adjoining catkins, whilst on another plant a hundred yards distant from the first all the barren flowers were withered up and ready to fall before the females could be seen.

Lexington, Kentucky JOHN DUNCAN

Thunderstorm at Preston

ON the 25th of last month a violent thunderstorm occurred at Preston, in Lancashire. The spire of St. Walburge's Church, which is, perhaps, the highest point in the town, was struck by lightning, some curious phenomena resulting. The lightning conductor, a rope composed of forty-two copper wires in six strands, was ruptured at about sixty feet from the ground. The wires were untwisted and spread out, the ends fused, and some of them turned up like hooks. The discharge passed obliquely through the tower wall for a distance of about three yards to a gas-pipe inside. In its passage it wrenched a piece of stone weighing 66lb. from an immense block, casting it to a distance of a hundred feet, besides literally tearing off other large masses. Before reaching the gas-pipe it projected some bricks against the opposite interior wall, shattering them to pieces. The gaspipe was severed and the lower portion curled completely round. Thence it passed to the gas-meter and dislocated many pipes beyond. The effect upon one leaden pipe was singular, holes were fused into it, in some cases right through, the molten metal being scattered about. Another discharge passed down a conductor at the west end of the church. The conductor itself was not ruptured, but a gas-pipe close to it was broken and a piece about a yard long was projected to a distance of forty feet, the gas meanwhile having ignited. Within the church, too, where there happened to be a leakage, the gas also ignited. It was further observed next morning that round about the church hundreds upon hundreds of worms were dead or dying.

Stonyhurst College STEPHEN WILLIAMS

Meteorology in Asia

IN NATURE, vol. iii. p. 473, it is said, "from Asia Minor we get no scientific records of weather." Perhaps you will pardon my informing your readers that the Turkish Government has eight telegraphic meteorological stations, besides its Central Observatory at Constantinople, under M. Aristide Coumbary. The stations are Sulina, Varna, Salonika, Fao, Bagdad, Smyrna, and Beyrout.

Two of these are in Asia Minor, and Beyrout is not far off. The observations are published monthly. In addition Mr. E. Purser, C.E., of the Smyrna and Aidin Railway Company, has published his observations for several years.

ROBERT H. SCOTT

A Wind Direction Rain Gauge

REFERRING to the paragraph in your number of March 30, p. 433, and Mr. Lyall's letter, April 6, p. 488, on Mr. Napier's "Wind Direction Rain Gauge," I beg to say that a gauge of a similar construction is in use at the Meteorological Observatory, Army Medical Department, Aldershot Camp. It was devised by the observer, Mr. John Arnold, A.H.C., F.M.S., about three years ago, so it would appear that the credit of the invention, if I may so term it, is due to no less than three parties, to each of whom I believe the matter was entirely original.

JOHN JAMES HALL, F.M.S.

Meteorological Observatory, Fulwell, near Twickenham, April 20

Spectra of Aurora, Corona, and Zodiacal Light

WHILE I am glad on my part to see Mr. Henry R. Procter's letter on the spectra of terrestrial aurora and solar corona in NATURE, p. 468, he may not be displeased on his to receive a confirmatory statement from an independent observer; and to this effect, viz., that whereas, firstly, the spectra of nineteen out of twenty auroras this winter have practically shown me nothing but one bright green line, and secondly, the spectrum of the solar corona, as seen during total eclipses, is said to be mainly characterised also by a similarly single vivid green line, yet it is not the same green line in the two cases, but a something widely, absolutely, physically, different.

I shall be glad, however, to be allowed still further on a branch of this subject, to ask, through the medium of NATURE's useful columns, whether anyone can kindly supply me with recent observations of the spectrum of the zodiacal light?

I have been trying for it in vain all this spring-time, and have now in despair given it up for the season. M. Angström—to whom be all honour for his first observation and correct description of the ordinary auroral spectrum—says that the zodiacal light spectrum shows the same green line as the aurora, viz., 1249 (Kirchhoff); but the eclipse observers, after proving that the corona is cosmical, solar, and the denser part of the zodiacal light,* might expect the latter rather to show the corona's green line, viz., 1474 (Kirchhoff).

This, however, the zodiacal light, according to M. Angström, does not. Is the zodiacal light then telluric and auroral, not solar and coronal? The measurement of the *place* of its green line should settle at once this most important and extensive physical question; and if the line be at any time visible at all, the large spectral distance between 1249 and 1474 (Kirchhoff's scale) would be sensible in the simplest apparatus. Yet, in these high latitudes the zodiacal light is always so extremely faint, so frequently altogether masked by auroral glows, and as yet, for its spectrum, depending, so far as I know, on only one observer, and he residing in quite an aurora-ridden part of the world, that it would seem to be a perfectly fair question to ask, "if any one else, besides the distinguished Natural Philosopher at Upsala, has observed the spectrum of the zodiacal light; and if so, how and where?"

C. PIAZZI SMYTH

Royal Terrace, Edinburgh, April 14

* [We venture to doubt this.—ED.]

Aurora by Daylight

I SEE that more than one of your correspondents in December numbers dispute the possibility of an aurora being seen by daylight. It doubtless is a rare occurrence, but two cases of the kind have come under my notice.

In December last my son saw what he took to be an aurora a little before sunset. He was at the time about three miles from home, and he had it constantly before him during his walk homewards, and saw it more and more developed as the darkness increased, so that there can be no doubt of the appearance before sunset being identical with what proved to be, as the night advanced, one of the most brilliant displays which we have had during a year very prolific in auroras. He states that after the sun had set, but whilst it was still quite light, the bright rose colour which distinguished that aurora was distinctly visible. The streamers that night proceeded from all parts of the heavens, meeting almost in the zenith, but what is very unusual, they were very much brighter in the east and south-east than in any other direction, which is probably the reason why they were so clearly visible whilst the sun was in the opposite quarter.

The other case came under my own observation in September 1849. Immediately after the sun had set, with a perfectly clear sky, I noticed three slightly diverging beams of light on the western horizon. One might almost have taken them for those beams from a setting sun which one sees much more often in pictures than in nature, had it not been that they did not emanate exactly from the spot where the sun had set, that they had an evident motion to the southward, and that two of them extended to the zenith, and finally down to the eastern horizon. It proved to be the most symmetrical auroral arch I ever saw. The perfect horizon I had to the west, and the straightness of its well-defined edges, joined to the facility which the double arch afforded of measuring the distance between the middle of each, immediately struck me as affording an opportunity of calculating its elevation above the earth, upon the supposition that the tapering away towards the horizon was the effect of perspective alone. I took steps therefore to measure the apparent width in the horizon and overhead, and also its rate of motion to the southward in both places, and by both methods the result was about 8 to 1. From these data, upon the assumption that it was a double ring everywhere equidistant from the earth's surface, and moving parallel to itself, I calculated the elevation, which came out 97 miles, and its rate of motion to the southward 656 miles per hour, the auroral meridian being N. 13° 15′ E., and the inclination of the plane of the arch to my horizon 94° 55′. These figures, whatever reliance can be placed on them, have nothing to do with the present question further than to show how bright the object must have been thus to attract my attention, and that, although the sun had set, there was still daylight enough for me to see the second hand of my watch, and to note the objects on an horizon some three or four miles distant, by which I measured the progress of the base of the arch, and the bearings of which I took the next day. Before it became really dark, the arch had become irregular, and detached streamers showed themselves in the usual form.

Ottawa JOHN LANGTON

UNIVERSITY INTELLIGENCE

OXFORD

QUEEN'S COLLEGE.—Mr. Charles Thomas Blanchard of Clifton College, was elected to a Scholarship in Natural Science in this College on Saturday last. *Proxime accessit*—Mr. William Percy Ashe, of Magdalene College School.

CORPUS CHRISTI COLLEGE.—There will be an Election to a Natural Science Fellowship in this College at the beginning of next Michaelmas Term. The examination will be specially in Chemistry, and will commence on Monday, Oct. 9 Candidates must have passed all the examinations required by the University for the degree of B A., and must not be in possession of any benefice or property which would disqualify for retaining a Fellowship. Candidates are requested to communicate with the President, either personally or by letter, at their convenience, before the end of Act Term.

Natural Science Lectures

The following Lectures will be given in addition to those noticed in our number for last week:—

Chemistry. Mr. Wyndham on the Elements of the Nitrogen, Boron, and Carbon groups, and their Combinations, on Thursdays and Saturdays at 11 A.M., at the University Museum.

Physiology. On General Physiology, with special reference to the microscopical anatomy and physiological chemistry of the elementary tissues. By Mr. Chapman. Mondays, Wednesdays, and Fridays, at 10 A.M, at the Magdalen College Laboratory.

Physics. On Elementary Mechanics and Hydrostatics. By Mr. Abbay. These lectures are free by mutual arrangement to members of these colleges at which either of these gentlemen is a lecturer, viz, to members of Merton, Magdalen, Jesus, and Wadham Colleges.

CAMBRIDGE

The following lectures in Natural Sciences are to be delivered at Trinity, St. John's, and Sidney Sussex Colleges during Easter term, 1871:—

On Heat. (For the Natural Sciences Tripos.) By Mr. Trotter, Trinity College, Monday, Wednesday, Friday, at 10, commencing Friday, April 28.

On Electricity and Heat. (For the Special Examination of the B.A. Degree.) By Mr. Trotter, Trinity College, Tuesday, Thursday, Saturday, at 10, commencing Tuesday, April 25. Students of Colleges other than Trinity, St. John's and Sidney, can be admitted on payment of a fee.

On Chemistry. By Mr. Main, St. John's College. Tuesday, Thursday, Saturday, at 12, commencing Thursday, April 27. Attendance on these lectures is recognised by the University for the certificate required by medical students previous to admission for the first examination for the Degree of M.B.

Instruction in Practical Chemistry will also be given.

On Geology. By Mr. Bonney, St. John's College.

1. Palæontology. Wednesdays and Fridays, at 9, commencing Friday, April 28.

2. Lyell's Principles of Geology. Tuesdays and Thursdays, at 9, commencing Thursday, April 27.

3. Elementary Lectures. Tuesdays and Thursdays, at 11, commencing Thursday, April 27. Students of other Colleges can be admitted to these lectures on payment of a fee.

On Botany (chiefly systematic and physiological.) By Mr. J. W. Hicks, Sidney College. Tuesday, Friday, Saturday, at 12, beginning Friday, April 28.

On Physiology. The Trinity Prælector in Physiology (Dr. M. Foster) will probably give a short course on Embryology at the New Museums, of which notice will be given.

The Physiological Laboratory will be open for practical instruction in Physiology daily. The lectures will be free to all Members of the University.

An election of a Superintendent of the Museums of Zoology and Comparative Anatomy was held on Tuesday, April 25, at one o'clock in the afternoon. This office was instituted in 1866, and was made tenable for five years; it is in the gift of the members of the electoral roll. The late superintendent, Mr. John Willis Clark, M.A. of Trinity College, was re-elected.

The Syndicate appointed November 17, 1870, "to consider whether any, and if so what, alterations may be made with advantage in the system of University examinations to enable persons who are unacquainted with the Greek language to obtain degrees," have issued an amended report. They recommend the substitution of French and German in place of Greek in the previous examination, at the option of the candidates. Every candidate who selects French and German will have to satisfy the examiners in papers containing passages from French and German authors for translation into English, with plain grammatical questions, and translate passages from English authors into French or German. In addition they will have to answer such questions on the Gospel selected for the Greek Testament subject and on matters collateral thereto as do not require a knowledge of the Greek language. The proposed alteration will come into force at the previous examination in the Lent Term, 1872. It will only affect those persons who proceed to a degree in honours; as a Greek classic the Acts of the Apostles in the original Greek are still retained as subjects in the general examination required of all candidates for the poll degree. A Grace, confirming the report of the Syndicate, will be offered to the Senate to-day.

The Board of Natural Science Studies have issued an amended report, recommending certain alterations in the examination for the Natural Sciences Tripos. They propose to separate the examination into two parts, and to continue it during eight days instead of six as heretofore. They also introduce a *viva voce* examination in addition to that by printed papers. The subjects of examination will be:—1, Chemistry and certain other branches of Physics; 2, Botany, including Vegetable Anatomy and Physiology; 3, Geology and Palæontology; 4, Mineralogy; 5, Comparative Anatomy, Physiology, and Zoology. The questions, exclusive of those which relate to practical work, will be comprised in twelve papers, and be so distributed that each of the papers will contain one or more questions in each of the following branches of science:—1, Chemistry and certain other branches of Physics; 2, Botany, including Vegetable Anatomy and Physiology; 3, Geology and Palæontology; 4, Mineralogy; 5, Comparative Anatomy, Physiology, and Zoology. Some of the questions will refer to objects exhibited at the examination. In the first six papers the questions will be of a more elementary character, and it will be open to the Board of Natural Sciences in any schedules which they may issue to indicate the subjects that shall be suitable for this part of the examination. In the last six papers the questions will take a wider range, yet still, so far as regards those branches for which schedules are issued by the Board of Natural Science Studies, will be confined to subjects indicated in the schedule; each of the last six papers will include a larger number of questions on the several subjects than the first six papers severally contain, and some of the questions will have special reference to the philosophy and history of those subjects. The Board further recommend that the foregoing alterations come into operation at the examination to be held in December, 1872.

EDINBURGH

The half-yearly meeting of the General Council of the University of Edinburgh was held on Tuesday, the Chancellor presiding. A report was given in with reference to the graduation in Arts, and, after some discussion, it was agreed by a majority to represent to the University Court that the degree of M.A. should be remodelled. The report of the committee recommending the establishment of a Chair of Celtic languages and literature was approved. A report was given in proposing that two additional members should be appointed to the Curatorial Court by the University Council. The report was adopted. It was resolved by a majority that the Council should represent to the University Court that it was advisable that the regulations with reference to degrees in law at present in force should be amended to the effect (1) of having two degrees in law attainable by examination, and (2) of not requiring for the lower degree a degree in Arts as a necessary preliminary. Some other business was transacted, after which the meeting separated.

NOTES

A PARAGRAPH has appeared in several papers stating that the venerable Professor of Geology in the University of Cambridge Prof. Sedgwick, purposed shortly vacating the chair. This announcement, we are credibly informed, is, to say the least, premature; and appears to have originated in a paragraph in the Professor's report to the University on the Museum under his charge. The words of this, however, do not necessarily imply more than that he begins to feel the burden of years heavy upon him; and in the University it is not believed that his resignation is imminent. Whether that come soon or late, all who have known how much he has done for the cause of natural science in the University will deeply regret it; and the fine collections in the Woodwardian Museum, amassed in great part during his tenure of the chair, and to no inconsiderable extent at his own expense, will long be a monument not unworthy of a life spent in the pursuit of science and in the service of his University.

THE subject for the Sedgwick prize, to be awarded in 1874, is "The Potton and Wicken phosphatic deposits and their general relation to the strata of Western Europe lying between the Portland beds and the Gault." The prize is open to all graduates who have resided sixty days during the twelve months preceding October 1, 1873. The essays are to be sent to the Registrary on or before October 1, 1873, privately with some motto prefixed, and to be accompanied by a sealed envelope with the same motto on the outside, enclosing a paper containing the name and college of the candidate. The prize was founded in 1865, by some friends of Dr. Adam Sedgwick, to encourage the study of geology. It consists of three years' interest on 500*l*. Scinde Railway Stock, but although subjects were proposed in 1867 and 1870, no essays were sent in.

THE Science and Art Department has issued a circular on the subject of the examinations in Ireland, which are henceforth to be placed on the same footing as those in England.

IN answer to several inquiries from America, we have great pleasure in stating that the report that the eminent astronomer, Leverrier, is reduced to great poverty, is entirely without foundation.

WE regret to record the death of William Wilson, the eminent bryologist, which took place at Warrington on the 3rd of April, in the 71st year of his age. Mr. Wilson is chiefly known as the author of "Bryologia Britannica," the standard work upon British mosses, which was published in 1855, and of which a second edition was in contemplation at the time of his decease. He took a high place as an authority upon mosses among continental botanists, and was in intimate communication with them. In the earlier portion of his life he devoted much attention to

British plants generally, and scattered papers in his name, often containing valuable observations in structure, may be found in the "Phytologist," and other botanical journals. He is frequently quoted by Sir W. J. Hooker, in the "British Flora," and contributed many specimens, accompanied by careful MS. notes, to the Hookerian Herbarium.

WE have received "Zur Erinnerung an Wilhelm Haidinger, von Franz Ritter v. Hauer," an eloquent tribute to the memory of the great mineralogist.

THE photographic papers record the death, at the early age of forty-seven, of Mr. T. R. Williams, one of the earliest photographic portraitists, and occupying the undisputed position of the most successful artist in his particular line. He was a pupil of Claudet's.

IN the first number of the "Zeitschrift für Ethnologie" of this year, is a very valuable list of works bearing on Mr. Darwin's theories, compiled by Spengel, which occupies twelve closely-printed octavo pages. First comes a list of translations into German of "The Origin of Species," of "Fertilisation of Orchids," and of "Variation of Animals and Plants;" next, forty-three original German works, criticising and carrying out the Darwinian theory. These are followed by about an equal number of books which refer to the same subject incidentally, though sometimes at considerable length. Among these we find Kupffer's "Essay on the Relation of Vertebrata to Ascidians," Von Baer's lectures, Carus's "Natur und Idee," and Rütimeyer's "Herkunft unserer Thierwelt." The fourth list is a most valuable one of reviews, magazine articles, and other scattered papers published in Germany on Natural Selection and the Descent of Man. Books devoted to the latter subject are next enumerated separately; and then translations into German of the kindred writings of Huxley, Lyell, Wallace, Agassiz, and Bates. Last comes a classified catalogue of all the works on Darwinism which have been published outside Germany, in England, France, Holland, and Italy. This list may be advantageously compared with that given by Mr. Darwin himself, in the 5th edition of the "Origin of Species." It will be invaluable to every student of the theory of evolution, and is a remarkable proof of the amount of scientific thought and work (as well as of some that is not scientific) which our great naturalist's writings have called forth.

A COMMUNICATION to the German Society of Anthropology during the past winter invokes the attention of all persons interested in science to the importance of making use of the opportunities for ethnological research furnished by the war between France and Germany; and the author, while acknowledging the difficulty of attending to such matters during the military operations, expresses his earnest hope that every possible effort may be made to secure a good series of the skulls and brains of the African tribes brought by France into the conflict, and especially those of the Turcos. We have not yet heard to what extent this suggestion was heeded by those who had the opportunity.

AT the last meeting of the Scientific Committee of the Horticultural Society, Mr. Alfred Smee introduced to the notice of the committee a new principle of boiler construction for heating hot-houses, &c. The peculiarity consisted in the use of only one pipe for the flow and return of the water, instead of two, as is usually the case. Mr. Smee finds that the difference in specific gravity between the hot and the cold water is quite sufficient to keep the two currents perfectly distinct, and to maintain for any length of time a free circulation at a uniform temperature. The principle is, of course, precisely the same as that of the polar and equatorial ocean currents, with respect to which so much has been said in our columns.

UNDER the title of the South London Microscopical and Natural History Club, a society has been formed to enable microscopists and lovers of natural history residing in the district to meet and interchange communications and specimens; by lectures and papers to afford instruction to the younger members in the use of the microscope, and preparation of objects, and to develop a taste for the study of zoology and botany; and by occasional excursions into the country around to investigate the natural productions of the district and procure fresh materials for observation, which eventually may lead to the formation of a cabinet and herbarium, illustrative of the indigenous fauna and flora of East Surrey. The first meeting was held on April 1, at Gloucester Hall, Brixton, and ordinary meetings are held on the first Tuesday in each month. We understand that the club already numbers more than a hundred members. The President is Mr. Henry Dean, F.L.S., Dr. Braithwaite is one of the Vice-Presidents, and Mr. Frederick Hovenden the Hon. Secretary. The annual subscription has been fixed at ten shillings.

SCIENCE is certainly popular in America. We have received the first number of the *American Journal of Microscopy*, devoted to the elucidation of Scientific and Popular Microscopy, edited by Dr. E. M. Hale, and published at Chicago. A trial number having been issued some months ago met with such a warm reception that the proprietors have determined on a regular monthly issue. The present number contains practical articles on the use of the microscope, and others descriptive of microscopic objects, some of them well illustrated. It promises to be a useful and interesting magazine.

ON February 4, an extraordinary meteor was seen at Pichicani in Peru. It was balloon-shaped, with the pointed end towards the earth, and red-coloured. It descended rapidly to the earth, and its descent was attended by an explosion, leaving a dense cloud over the place. It injured the roofs of several huts, and knocked down a fence for about 500 yards. On the spot, it is reported several dead fish were found of different species, which are supposed to have been lifted out of the river, and dashed against the stones. Similar events happened near Huanochullo and Atucachi.

ON February 22, several shocks of earthquake were felt at Puno in Peru, and on March 6, a slight earthquake of thirty seconds after rain.

IN March a most remarkable electric storm was witnessed at Tacua in Peru. For a few hours the snowy peak of Tacora seemed the centre of conflagration of lightning, nor was the thunder less terrific. The population were the more alarmed as the night before there had been some slight shocks of earthquake.

THE horned toad of Oregon (*Tapaya Douglassii*) is a remarkable creature, plentiful on the open plains of the district among rocks and sand. They are usually grey, but Dr. Cooper states that he met with one example which was of a brick red on the back, but beneath white like the rest. These colours resemble those of the stones among which they live, and it is supposed that they have the chameleon-like property of changing their hue. Though ferocious in appearance, they are perfectly harmless; yet the Indians believe them to have the power of producing a poisonous wound with their blunt spines, just as, among ourselves, the newts are credited with many objectionable qualities. These toads are very slow in motion, and do not attempt to bite. One was kept in captivity for five months without food in a small box, remaining quite lively for the greater part of the time. When irritated, it would spring in a most threatening manner at anything pointed at it, at the same time opening its mouth wide and hissing audibly, after which it would inflate its body, and show other marks of anger.

THE Western gull (*Larus occidentalis*) is very abundant on the whole coast of California, especially on the Farrallone

Islands, where it is a serious hindrance to the men employed in collecting the eggs of the Murre (*Uria Brunnichii* which breeds there in countless numbers. The traffic in their eggs between these islands and San Francisco alone reaches annually the sum of between one and two thousand dollars. The egg-hunters meet at one o'clock every day during the season (from May to July) with the exception of Sundays and Thursdays, and at a given signal, so that each may have an equal chance in gathering the spoil, start off for the most productive egging grounds. The gulls understanding, it would seem, what is to occur, hover overhead, awaiting the advance of the men, who rush eagerly into the rookeries. The affrighted Murres have scarcely risen from their nests, before the gull, with remarkable instinct, flying but a few paces ahead of the hunter, alights on the ground, tapping such eggs as the short time will allow before the egger comes up with him. The broken eggs are passed by the men, who remove only those which are sound. The gull then returning to the field of its exploits, procures a plentiful supply of its favourite food. Dr. Heermann says that he once saw three gulls scientifically approach a single Murre sitting on her egg. Two of them feigning an attack in front, the Murre raised herself to repel them; instantly the third advancing from the rear seized her solitary egg from beneath her, and flew off with the booty, the two first immediately following to claim their share. The egg was dropped and broke on the rocks, when a general scramble ensued between the three robbers for the valued prize.

AMONG the plants which have received honour and religious veneration among the Hindoos, the Doob-grass (*Cynodon dactylon*) holds a prominent place. Its usefulness, added to its beauty, induced them in their earliest ages to consider it the abode of a benevolent nymph, and it is employed in many of their religious ceremonies. It owes much of its honour to its great tenacity of life, being regarded as an emblem of immortality; and the Véda celebrates it, under one of its names, in words which indicate its supposed mystic origin :—"May *Durvà*, which rose from the water of life, which has a hundred roots and a hundred stems, efface a hundred of my sins, and prolong my existence for a hundred years." The extreme rapidity of growth in this grass is here referred to, and it is stated that, by merely chopping it in pieces and sprinkling these on prepared ground, a verdant sward may be obtained in a few weeks. The Doob-grass is frequently introduced by name in the popular stories of the country, and the roots are esteemed medicinal.

IN the northern district of Alaska the various grasses, which form an important portion of the vegetation, are woven into mats, dishes, articles of summer clothing, such as socks, mittens, and hats, by the Indians and Esquimaux. Mr. W. H. Dall states in his report upon the resources of that region, that in winter the grasses are neatly tied in bunches, and shaped to correspond with the foot; they are then placed between the foot and the sealskin sole of the winter boots worn in that country. "There they serve as a non-conductor, keeping the foot dry and warm, and protecting it from contusion to an extent which the much-lauded moccasins of the Hudson Bay men never do. In fact, I believe the latter to be, without exception, the worst, most uncomfortable, and least durable covering for the foot worn by mortal man."

AMONG other South American districts reported on the point of being reworked are the Cinnabar mines of Santa Barbara in Huancavolico, in Peru, gold and silver mines in Cauca, and copper mines in Doepar, in Colombia or New Granada.

THE Chilian Government has employed the *Cavadonga* war vessel, Captain Gormaz, on surveying duties. Her work begins at Ancud.

THE TRANSITS OF VENUS IN 2004 AND 2012 *

WHILE preparations are being made by astronomers of various nations for the observation of the approaching Transit of Venus over the sun's disc in December 1874, it may be of interest to know under what conditions the pair of transits in the twenty-first century will take place. This consideration has induced me to make a careful calculation of the circumstances of the transits in 2004 and 2012, from M. Leverrier's Tables of the Sun and Planet, which at present are extremely accurate, and which there can be little doubt will closely represent the phenomena to be witnessed in those years. The calculations have been made entirely by myself, but with every precaution to avoid error, and I have confidence in the results.

The following are the resulting elements of the transit in 2004 :—

Greenwich mean time of conjunction in right ascension 2004, June 7d 20h 51m 28s·8.

		° ′ ″
Right Ascension of Sun and Venus	. .	76 50 28·96
Declination of Sun	. .	+22 53 20·4
,, Venus	.	+22 42 52·3
Horary motion in R.A. . . . Sun	. .	2 35·07
,, . . Venus	.	−1 47·40
Horary motion in declination Sun	. .	+0 13·00
,, ,, Venus	.	−0 43·83
Semi-diameter . Sun	. .	15 45·74
,, . Venus	.	28·75
Horizontal parallax . . . Sun	. .	8·78
,, . . . Venus	.	30·85
Log. distance of Venus from the Earth	.	9·46069

Equation of time . 1m 15s·6 (additive to mean time).

Hence, for the centre of the earth,

		d	h	m	s		°	
First external contact =	June	7	17	3	43	at	115·0	For the *direct* image.
from N. towards E.								
First internal contact =	June	7	17	22	35	at	118·0	
from N. towards E.								
Second internal contact =	June	7	23	5	40	at	214·6	
from N. towards E.								
Second external contact =	June	7	23	24	32	at	218·5	
from N. towards E.								

And l being the geocentric latitude, ρ the radius of the earth at any place, and λ the longitude from Greenwich + E, − W., the reductions for parallax will be obtained from

1st ext. cont. = June 7d 17h 3m 43s $+ [2·2198]\rho \, . \sin l - [2·5932] \, . \rho \, . \cos l \, . \cos(\lambda + 176° \; 32')$.

1st int. cont. = June 7d 17h 22m 35s $+ [2·2571]\rho \, . \sin l - [2·5765] \, . \rho \, . \cos l \, . \cos(\lambda + 182° \; 38')$.

2nd int. cont. = June 7d 23h 5m 40s $- [2·5090]\rho \, . \sin l + [2·4353] \, . \rho \, . \cos l \, . \cos(\lambda + 47° \; 17')$.

2nd ext. cont. = June 7d 23h 24m 32s $- [2·4928]\rho \, . \sin l + [2·4631] \, . \rho \, . \cos l \, . \cos(\lambda + 54° \; 35')$.

For the Royal Observatory, Greenwich, I find :—

			d	h	m	s	
First external contact,	June		7	17	9	56	Mean times at Greenwich.
,, internal	,,	,,		17	28	51	
Second internal	,,	,,		23	3	24	
,, external	,,	,,		23	22	15	

Therefore the entire transit will be visible at Greenwich.

Similarly, the elements of the transit of 2012 are found to be: Greenwich mean time of conjunction in right ascension 2012, June 5d 13h 4m 44s·3.

		° ′ ″
Right ascension of Sun and Venus	. .	74 31 11·9
Declination of Sun	. .	+22 40 24·1
,, Venus	. .	+22 50 3·0

,, . Venus	. .	28·77
Horizontal parallax..............Sun	. .	8·76
,, ,, Venus	. .	30·86
Log. distance of Venus from the Earth	.	9·46042

Equation of time . 1m 19s·8 (additive to mean time).

* "Note on the Circumstances of the Transits of Venus over the Sun's Disc in the years 2004 and 2012." From the Proceedings of the Royal Society.

Hence, for the centre of the earth,

		d	h	m	s		
First external contact from N. towards E.	... June	5	10	22	11	at 40°·3	
First internal contact from N. towards E.	... June	5	10	39	56	at 37·8	For the *direct* image
Second internal contact from N. towards E.	... June	5	16	42	6	at 293·1	
Second external contact from N. towards E.	... June	5	17	0	0	at 290·5	

And, with the same notation as before, I find for the reduction for parallax,

1st ext. cont. = June 5d 10h 22m 11s + $[2·4536]\,\rho\,.\sin l - [2·4582]\,.\,\rho\,.\cos l.\,\cos(\lambda + 41°\ 28')$.

1st int. cont. = June 5d 10h 39m 56s + $[2·4838]\,\rho\,.\sin l - [2·4558]\,.\,\rho\,.\cos l.\,\cos(\lambda + 43°\ 52')$.

2nd int. cont. = June 5d 16h 42m 6s − $[2·1301]\,\rho\,.\sin l + [2·5968]\,.\,\rho\,.\cos l.\,\cos(\lambda - 10°\ 57')$.

2nd ext. cont. = June 5d 17h 0m 0s − $[2·1158]\,\rho\,.\sin l + [2·5825]\,.\,\rho\,.\cos l.\,\cos(\lambda - 6°\ 28')$.

At Greenwich the egress only will be visible.

		d		h	m	s	
Last internal contact	June	5	at	16	44	23	Mean times at Greenwich.
,, external	,,	,,	at	17	2	15	

The sun will rise at 15h 46m.

J. R. HIND

AMERICAN NOTES

THE year 1871 bids fair to be marked in the history of American science for the great number of exploring expeditions under the auspices of the United States Government. First, that of Captain C. F. Hall, the well-known Arctic traveller, for whose proposed Polar Exploration the United States steamer *Periwinkle* is now being prepared at the Washington Navy-yard. This vessel, of nearly four hundred tons burden, is said to be very staunch and reliable, and her equipment will be of the best order. It is understood that the expedition will start about the end of May, and that Captain Hall's scientific assistants will be Dr. David Walker, formerly known as the surgeon and physicist of Sir Leopold M'Clintock's expedition in the *Fox*, and Dr. Emil Bessels, who has seen Arctic service in a Spitzbergen expedition. Dr. F. V. Hayden, long known to the public as a geologist and explorer, continues his labours of the past season, with the aid of an appropriation by Congress of 40,000 dols. His party is now being fitted out, and will be provided with the necessary assistants in all branches of research. His work will be to the northward of the scene of his last year's explorations. A third expedition is that of Lieutenant G. M. Wheeler, which, under the direction of the War Department, proceeds to explore certain little-known regions of Arizona and Southern Nevada, including the country about the Lower Colorado and Bill Williams Fork. This work will require several years for its completion. Lastly, Major Powell continues his labours during the present season, and expects to make a careful examination of the Canons of Green River as well as of the Colorado.—Attention was called some time ago to the high scientific value of the collection of objects made by the late Dr. Klemm, of Dresden, for use in his "History of the Progress of Human Civilisation;" and it was suggested that in its great extent, and in the harmonious exhibition of illustrations of human art and handicraft in every department, it would constitute an important addition to the means of instruction in the city of New York. An association of parties in Leipsic has accomplished its purchase, at a cost of over ten thousand dollars; and has determined to make it the basis of an international anthropological museum, which, it is expected, will be one of the most complete in the world. Contributions from all parts of the globe, and especially from America, are invited by the committee having the matter in charge, and we trust that the appeal will not be in vain. —Stimulated by the success of the experiment made by the Philadelphians in stocking the Delaware River with black bass, some public-spirited gentlemen of Reading, Pennsylvania, have undertaken to try the same experiment in the Schuylkill, and 350 dollars have already been subscribed for that purpose.—The town of Amherst, in Massachusetts, has followed the example of New York, Philadelphia, Boston, and other places, in introducing English sparrows, in the hope of establishing a colony of these birds.—The San Francisco papers are calling attention to specimens of fossil ivory brought from Alaska; and parties are said to be about entering upon the business of collecting it on a large scale. This ivory consists of the tusks of the mammoth or fossil elephant (*Elephas primigenius*), the remains of which are extremely abundant in Alaska, but much more so in Siberia, from which latter country, as is well known, an appreciable percentage of all the ivory now used in the arts is obtained.—The College of the City of New York in Twenty-third Street, shows a commendable desire to increase its means of instruction in natural history, and particularly in the department of osteology, the president having succeeded by unremitting effort in obtaining means to secure quite a large number of specimens, among which may be especially mentioned a large slab of stone containing a well-preserved skeleton of the *Ichthyosaurus*, or fish-like fossil lizard from the Lias of Germany. The specimen is about ten feet long, and, from its perfection and excellence of preservation, is justly entitled to consideration.

EXPERIMENTS ON THE SUCCESSIVE POLARISATION OF LIGHT, WITH DESCRIPTION OF A NEW POLARISING APPARATUS *

THE term successive polarisation was applied by Biot to denote the effects produced when a ray of polarised light is transmitted through a plate of rock-crystal cut perpendicularly to the axis, or through limited depths of certain liquids. In these cases the plane of polarisation is found to be changed on emergence, and differently for each homogeneous ray, so that, when white light is employed, on turning the analyser round continuously in one direction different colours successively appear, rising or falling in the scale according to the nature of the substance.

If, while the analyser is turned from left to right, the tints ascend (*i.e.* follow the order R, O, Y, G, B, P, V), the substance is said to exhibit right-handed successive polarisation, but if the tints descend, the successive polarisation is said to be left-handed.

These phenomena were satisfactorily explained by Fresnel in the following way. The incident polarised ray, instead of resolving itself into two plane polarised rays at right angles to each other, as in the ordinary cases of dipolarisation, resolves itself in these instances into two circularly polarised rays, one right-handed the other left-handed, which are transmitted with different velocities; each homogeneous ray, thus resolved into two opposite circularly polarised pencils, on emergence composes a ray polarised in a single plane, the deviation of which from the primitive plane of polarisation depends on the difference of phase of the two circularly polarised rays on emergence.

The rotation of the planes of polarisation is from left to right or from right to left, according to whether the right-handed or left-handed circular rays are transmitted with the greater velocity.

The term dipolarisation, proposed by Dr. Whewell to express the bifurcation which a ray of polarised light suffers when it is transmitted through a crystallised plate, is a very appropriate one; but as there are different kinds of such separation, we may designate plane dipolarisation the resolution into two plane-polarised rays at right angles to each other, and circular dipolarisation the resolution into two circularly polarised rays, one right-handed the other left-handed. In like manner the term elliptic dipolarisation may be employed to represent the phenomena shown by transmitting a polarised ray through a plate of rock-crystal obliquely to the axis.

The object of the present communication is to make known another means of producing successive polarisation, both right-handed and left-handed, which, equally with the well-known modes, may be proved to arise from the interference of two opposite systems of circularly polarised rays.

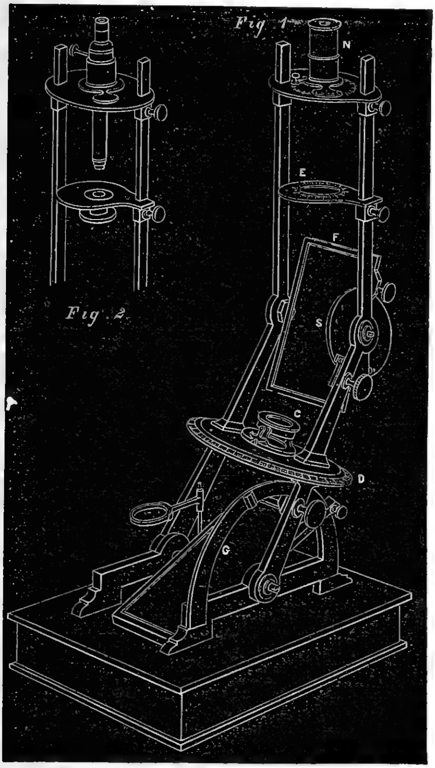
The polarising apparatus which I have employed for the experiments I am about to detail is represented by Fig. 1.

A plate of black glass, G, is fixed at an angle of 3° to the horizon. The film to be examined is to be placed on a diaphragm, D, so that the light reflected at the polarising angle from the glass plate shall pass through it at right angles, and after reflection at an angle of 18° from the surface of a polished silver

* From the Proceedings of the Royal Society.

plate S, shall proceed vertically upwards. N is a Nicol's prism, or any other analyser, placed in the path of the second reflection. The diaphragm is furnished with a ring, moveable in its own plane, by which the crystallised plate to be examined may be placed in any azimuth. C is a small moveable stand, by means of which the film to be examined may be placed in any azimuth and at any inclination; for the usual experiments this is removed.

If a lamina of quartz cut parallel to the axis, and sufficiently thin to show the colours of polarised light, be placed upon the diaphragm so that its principal section (*i.e.* the section containing the axis) shall be 45° to the *left* of the plane of reflection, on turning the analyser from left to right, instead of the alternation of two complementary colours at each quadrant, which appear in the ordinary polarising-apparatus, the phenomena of successive polarisation, exactly similar to those exhibited in the ordinary

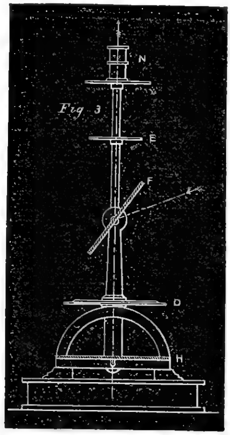


apparatus by a plate of quartz cut perpendicular to the axis will be exhibited: the colours follow in the order R, O, Y, G, B, P, V, or, in other words, ascend as in the case of a right-handed plate of quartz cut perpendicularly to the axis. If the lamina be now either inverted, or turned in its own plane 90°, so that the principal section shall be 45° to the right of the plane of reflection, the succession of the colours will be reversed, while the analyser moves in the same direction as before, presenting the same phenomena as a left-handed plate of quartz cut perpendicularly to the axis. Quartz is a positive doubly refracting crystal, and in it consequently the ordinary index of refraction is smaller than the extraordinary index. But if we take a lamina of a negative crystal, in which the extraordinary index is the least, as a film of Iceland spar split parallel to one of its natural cleavages, the phenomena are the reverse of those exhibited by quartz; when the principal section is on the *left* of the plane of reflection the colours descend, and when it is on the *right* of the same plane the colours ascend, the analyser being turned from left to right.

It has been determined that the ordinary ray, both in positive and negative crystals, is polarised in the principal section while the extraordinary ray is polarised in the section perpendicular thereto. It is also established that the index of refraction is inversely as the velocity of transmission. It follows from the above experimental results, therefore, that when the resolved ray whose plane of polarisation is to the left of the plane of reflection is the quickest the successive polarisation is right-handed, and when it is the slowest the successive polarisation is left-handed; in the order R, O, Y, G, B, P, V, and in the second case in the reversed order.

The rule thus determined is equally applicable to laminæ of biaxal crystals.

As selenite (sulphate of lime) is an easily procurable crystal, and readily cleavable into thin laminæ capable of showing the colours of polarised light, it is most frequently employed in experiments on chromatic polarisation. The laminæ into which this substance most readily splits, contain in their planes the two



optic axes; polarised light transmitted through such laminæ is resolved in two rectangular directions, which respectively bisect the angles formed by the two optic axes; the line which bisects the smallest angle is called the intermediate section, and the line perpendicular thereto which bisects the supplementary angle is called the supplementary section. These definitions being premised, if a film of selenite is placed on the diaphragm, with its intermediate section to the left of the plane of reflection, the successive polarisation is direct or right-handed; if, on the contrary, it is placed to the right of that plane, the successive polarisation is left-handed. The ray polarised in the intermediate section is therefore the most retarded; and as that section is considered to be equivalent to a single optic axis, the crystal is positive.

In one kind of mica the optic axes are in a plane perpendicular to the laminæ. They are inclined 22½° on each side the perpendicular within the crystal, but owing to the refraction, are seen respectively at an angle of 35°·3 therefrom.

The principal section is that which contains the two optic axes. If the film is placed on the diaphragm with its principal section inclined 45° to the left of the plane of reflection, the successive polarisation is right-handed. The ray therefore polarised in the section which contains the optic axes is the one transmitted with the greatest velocity.

Films of uniaxal crystals, whether positive or negative, and of biaxal crystals, all agree therefore in this respect; that if the plane of polarisation of the quickest ray is to the left of the plane of reflection, the successive polarisation is right-handed when the analyser moves from left to right, and if it is to the right of the plane of refraction, other circumstances remaining the same, the successive polarisation is left-handed.

It must be taken into consideration that the principal section of the film is inverted in the reflected image, so that if the plane of polarisation of the quickest ray in the film is to the left of the plane of reflection, it is to the right of that plane in the reflected image.

It may not be uninteresting to state a few obvious consequences of this successive polarisation in doubly refracting laminæ, right-handed and left-handed according to the position of the plane of polarisation of the quickest ray. They are very striking as experimental results, and will serve to impress the facts more vividly on the memory.

1. A film of uniform thickness being placed on the diaphragm with its principal section 45° on either side the plane of reflection, when the analyser is at 0° or 90°, the colour of the film remains unchanged, whether the film be turned in its own plane 90°, or be turned over so that the back shall become the front surface; but if the analyser be fixed at 45°, 135°, 225°, or 315°, complementary colours will appear when the film is inverted from back to front, or rotated in its own plane either way 90°.

2. If a uniform film be cut across and the divided portions be again placed together, after inverting one of them, a compound film (fig 4) will be formed, which, when placed on the diaphragm, will exhibit simultaneously both right-handed and left-handed successive polarisation. When the analyser is at 0° or 90° the colour of the entire film uniform; as it is turned round the tints of one portion ascend, while those of the other descend; and when the analyser is at 45° or n90° + 45°, they exhibit complementary colours.

3. A film increasing in thickness from one edge to the other is well suited to exhibit at one glance the phenomena due to films of various thicknesses. It is well known that such a film placed between a polariser and an analyser will show, when the two planes are parallel or perpendicular to each other, and the principal section of the film is intermediate to these two planes, a series of parallel coloured bands, the order of the colours in each band from the thick towards the thin edge being that of their refrangibilities, or R, O, Y, G, B, P, V. The bands seen when the planes are perpendicular, are intermediate in position to those seen when the planes are parallel; on turning round the analyser these two systems of bands alternately appear at each quadrant, while in the intermediate positions they entirely disappear.

Now let us attend to the appearances of these bands when the wedge-form film is placed on the diaphragm of the instrument, Fig. 1. As the analyser is moved round the bands advance towards or recede from the thin edge of the wedge without any changes occurring in the colours or intensity of the light, the same tint occupying the same place at every half revolution of the analyser. If the bands advance towards the thin edge of the wedge, the successive polarisation of each point is left-handed; and if they recede from it the succession of colours is right-handed; every circumstance, therefore, that with respect to a uniform film changes right-handed into left-handed successive polarisation, in a wedge of the same substance transforms receding into advancing bands, and *vice versâ*. These phenomena are also beautifully shown by concave or convex films of selenite or rock-crystal, which exhibit concentric rings contracting or expanding in accordance with the conditions previously explained.

4. Few experiments in physical optics are so beautiful and striking as the elegant pictures formed by cementing laminæ of selenite of different thicknesses (varying from $\frac{1}{2000}$ to $\frac{1}{50}$ of an inch) between two plates of glass. Invisible under ordinary circumstances, they exhibit, when examined in the usual polarising apparatus, the most brilliant colours, which are complementary to each other in the two rectangular positions of the analyser. Regarded in the instrument, Fig. 1, the appearances are still more beautiful; for, instead of a single transition, each colour in the picture is successively replaced by every other colour. In preparing such pictures it is necessary to pay attention to the direction of the principal section of each laminæ, when different pieces of the same thickness are to be combined together to form a surface having the same uniform tint; otherwise in the intermediate transitions the colours will be irregularly disposed.

5. A plate of rock-crystal cut perpendicular to the axis loses its successive polarisation, and behaves exactly as an ordinary crystallised film through which rectilinear polarised light is transmitted.

6. A thick plate of unannealed glass undergoes a series of regular transformation,

The phenomena of successive or rotatory polarisation I have experimentally demonstrated admit of a very simple explanation.

The polarised light incident on the crystallised plate is resolved into two portions of equal intensity polarised at right angles to each other; one in the principal section, the other perpendicular thereto. These resolved portions, when they fall on the silver plate, have their planes of polarisation each at an azimuth of 45°, one to the right, the other to the left of the plane of reflection. These are again resolved in the planes of reflection and the plane perpendicular thereto, and are in consequence of the unequal retardation, which in silver at an angle of 72° amounts to a quarter of an undulation, converted into circularly polarised beams, one right-handed, the other left-handed.

The various homogeneous rays being accelerated differently in their transmission through the two sections of the crystallised plate this difference is preserved after reflection from the silver plate, and the oppositely circularly polarised beams are reflected with the same difference of phase as the two plane-polarised rays are when emerging from the crystallised lamina. The composition of two circular waves, one right-handed the other left-handed, gives for resultant a plane wave, the azimuth of which varies with the difference of phase of the two components.

When the plane of polarisation does not lie equally between the two rectangular sections of the laminæ, these still remaining 45° from the plane of reflection of the silver plate, the beam is resolved into two unequal portions, the amplitudes of which are as sin a, to cos a.

Each therefore gives rise to a circular undulation of different amplitude. The resultant of two opposite circular undulations of different amplitudes is an ellipse of constant form, the axes of which vary in position according to the difference of phase. The same phenomena of successive polarisation are therefore exhibited in whatever azimuth the laminæ is turned in its own plane, but the tints become fainter and fainter until ultimately, when the principal or perpendicular section is parallel to the plane of reflection of the polarising plate, all colour disappears.

By means of the phenomena of successive polarisation it is easy to determine which is the thicker of two films of the same crystalline substance. Place one of the films on the diaphragm (a) of the instrument (Fig. 1 a) in the position to show, say, right-handed polarisation, then cross it with the other film; if the former be the thicker, the successive polarisation will be still right-handed; if both be equal there will be no polarisation; and if the crossed film be the thicker, the successive polarisation will be left-handed. In this manner a series of films may be readily arranged in their proper order in the scale of tints.

In the experiments I have previously described the planes of reflection of the polarising-mirror and of the silver plate were coincident; some of the results obtained when the azimuth of the plane of reflection of the silver plate is changed are interesting.

I will confine my attention here to what takes place when the plane of reflection of the silver plate is 45° from that of the polarising-reflector.

When the principal sections of the film are parallel and perpendicular to the plane of reflection of the polarising mirror, as the whole of the polarised light passes through one of the sectio ns no interference can take place, and no colour will be seen, whatever be the position of the analyser.

When the principal sections of the film are parallel and perpendicular to the plane of reflection of the silver plate, they are 45° from the plane of reflection of the polarising mirror.

The polarised ray is then resolved into two components polarised at right angles to each other, one component is polarised in the plane of reflection of the silver plate, the other perpendicular thereto; and one is retarded upon the other by a quarter of an undulation.

When the analyser is 0° or 90° no colours are seen, because there is no interference; but when it is placed at 45° or 135°, interference takes place, and the same colour is seen as if light circularly polarised had been passed through the film. The bisected and inverted film shows simultaneously the two complementary colours.

But when the film is placed with one of its principal sections 22½° from the plane of reflection of the polarising-mirror, on turning round the analyser the appearances of successive polarisation are reproduced exactly as when the planes of reflection of the silver plate and of the polarising-mirror coincide. In this case the components of the light oppositely polarised in the two sections are unequal, being as cos $22\frac{1}{2}°$ to sin $22\frac{1}{2}°$; these components respectively fall $22\frac{1}{2}°$ from the plane of reflection of the silver plate and from the perpendicular plane, and are each resolved in the same proportion in these two planes. The weak component of the first, and the strong component of the second, are resolved into the normal plane, while the strong component of the first and the weak component of the second are resolved into the perpendicular plane.

As bearing intimately on the subject of this paper, I will here quote a passage from a memoir presented by Fresnel to the French Academy of Sciences in 1817, and published, in abstract, in the "Annales de Chimie," t. xxviii., 1825:—

"If a thin crystallised plate be placed between two parallelopipeds of glass crossed at right angles, in each of which the light previously polarised undergoes two total reflections at the incidence of $54\frac{1}{2}°$, first before its entrance into the plate (which we suppose perpendicular to the rays), and subsequently after its emergence; and if, besides, the plate be turned so that its axis makes an angle of 45° with the two planes of double reflection, this system will present the optical properties of plates of rock crystal perpendicular to the axis, and of liquids which colour polarised light. When the principal section of the rhomboid with which the emergent light is analysed is turned round, the two images will gradually change colour, instead of experiencing only simple variations in the vividness of their tints, as occurs in the ordinary case of thin crystallised plates; besides, the nature of these colours depends only on the respective inclination of the primitive plane of polarisation and the principal section of the rhomboid, that is to say, of the two extreme planes of polarisation; thus, when this angle remains constant, the system of the crystallised plate and the two parallelopipeds may be turned round the transmitted pencil without changing the colour of the images. It is this analogy between the optical properties of this little apparatus and those of plates of rock-crystal perpendicular to the axis which enabled M. Fresnel to foresee the peculiar characters of double refraction that rock-crystal exerts on rays parallel to the axis."

It does not appear that Fresnel, in any of his published memoirs, has given any further modifications of this experiment, the importance of which has been almost entirely overlooked in elementary treatises on light. He does not seem to have remarked that similar phenomena of successive polarisation are exhibited when the light incident on the crystallised plate is plane polarised, nor that the order of the succession of the colours depends on the position of the principal section with respect to the plane of polarisation. These circumstances are indeed necessarily included in the beautiful theory established by this eminent philosopher; but I am not aware that they have hitherto been specifically deduced or experimentally shown.

The apparatus (Fig. 1) affords also the means of obtaining large surfaces of uncoloured or coloured light in every state of polarisation, rectilinear, elliptical, or circular.

It is for this purpose much more convenient than a Fresnel's rhomb, with which but a very small field of view can be obtained. It must, however, be borne in mind that the circular and elliptical undulations are inverted in the two methods; in the former case they undergo only a single, in the latter case a double reflection.

For the experiments which follow, the crystallised plate must be placed on the diaphragm E between the silver plate and the analyser, instead of as in the preceding experiments, between the polariser and the silver plate.

By means of a moving ring within the graduated circle D the silver plate is caused to turn round the reflected ray, so that while the plane of polarisation of the ray remains always in the plane of reflection of the glass plate, it may assume every azimuthal position with respect to the plane of reflection of the silver plate. The film to be examined and the analyser move consentaneously with the silver plate, while the polarising mirror remains fixed.

In the normal position of the instrument the ray polarised by the mirror is reflected unaltered by the silver plate; but when the ring is turned to 45°, 135°, 225°, or 315°, the plane of polarisation of the ray falls 45° on one side of the plane of reflection of the silver plate, and the ray is resolved into two others polarised respectively in the plane of reflection and the perpendicular plane, one of which is retarded on the other by a quarter of an undulation, and consequently gives rise to a circular ray, which is right-handed or left-handed according to whether the ring is turned 45° and 225°, or 135° and 315°. When the ring is turned so as to place the plane of polarisation in any intermediate position be-tween those producing rectilinear and circular light, elliptical light is obtained on account of the unequal resolution of the ray into its two rectangular components.

Turning the ring of the graduated diaphragm from left to right when the crystallised film is between the silver plate and the analyser, occasions the same succession of colours for the same angular rotation as rotating the analyser from right to left when the instrument is in its normal position, and the film is between the polariser and the silver plate.

To arrange the apparatus for the ordinary experiments of plane-polarised light without the intervention of the silver plate, all that is necessary is to remove the silver plate from the frame F, and to substitute for it a plate of black glass, which must be fixed at the proper polarising-angle.

To convert it into a Norrenberg's polariser, a silver mirror must be laid horizontal at H, and the instrument straightened, as shown at Fig. 3, so that a line perpendicular to the mirror shall correspond with the line of sight. The silver plate must be removed from the frame F, and a plate of transparent glass substituted for it, which must be so inclined that the light falling upon it shall be reflected at the polarising-angle perpendicularly towards the horizontal mirror. The eye will receive the polarised ray reflected from the mirror, and the polarised ray will have passed, before it reaches the eye, twice through a crystallised plate placed between the mirror and the polariser. The result is the same as if, in the ordinary apparatus, the polarised plate had passed through a plate of double the thickness.

Fig. 2 shows the addition to the apparatus when the coloured rings of crystals are to be examined by light circularly or elliptically polarised; *a* is the optical tube containing the lenses, which require no particular explanation, and *b* the condenser over which the plate is to be placed.

C. WHEATSTONE

SCIENTIFIC SERIALS

IN the *Journal of Botany* for April, Mr. Hiern concludes his exhaustive paper On the Forms and Distribution over the World of the Batrachian Section of *Ranunculus*; Mr. J. G. Baker his Monograph of the Liliaceous genus *Xiphion*; and we have also the conclusion of the valuable List of New Species of Phanerogamous plants published in Great Britain during the year 1870. Mr. Hiern's paper concludes with a mathematical statement of the form of the leaf of water-plants dependent on the strength of the current. Mr. Carruthers reviews the Contributions to Fossil Botany published in Britain in 1870, which are very few in number.

IN the *Scottish Naturalist* for April, Dr. Lauder Lindsay commences his second paper on Natural Science Chairs in our Universities, and the editor, Dr. Buchanan White, concludes his details of "Sugaring, how, when, and where to do it." Under the head of zoology, Dr. D. Sharp gives an interesting account of the Coleoptera of the Scotch Fir, and Mr. Robert Gray a history of the Capercaillie. The contributions to phytology are a short paper on Scottish plant-names; and a List of Mosses found in the vicinity of Forres, by the Rev. James Keith. Some of the shorter paragraphs contain also interesting information. We would suggest to the conductors of the *Naturalist* whether it is not possible to avoid the very objectionable practice of dividing their papers in the very middle of a sentence. The present number commences ". . . . waist." in the midst of the Editor's article on Sugaring, and concludes "Knowledge is likely to . . . ." in Dr. Lauder Lindsay's on the University Chairs. It is too great a stretch on the memory to expect an incomplete sentence to be kept in the head for three months; and the previous number is not always at hand to remind one of the connection.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 20.—"Research on a New Group of Colloid Bodies, containing Mercury, and certain members of the series of Fatty Ketones." By J. Emerson Reynolds, M.R.C.P. Edin., &c.

"On the Existence and Formation of Salts of Nitrous Oxide." By Edward Divers, M.D.

Geologists' Association, April 10.*—A numerous party of the members of the Geologists' Association visited Cambridge for the purpose of inspecting the Woodwardian Museum and the exposures of Cretaceous strata in the neighbourhood. On arriving at Cambridge the party proceeded at once to the Woodwardian Museum, where they were met by the Rev. Dr. Cookson, Master of St. Peter's College, the Rev. J. Wiltshire, M.A., President of the Association, Prof. Morris, the Rev. T. G. Bonney, Fellow and Tutor of St. John s College, the Rey. Osmond Fisher, M.A., and Rev. Harry Seeley, F.G.S., as the representative of the venerable Prof. Sedgwick, who, much to his regret, was prevented being present. The fine collection of fossil mollusca was ably described by the Rev. T. G. Bonney, and the reptilian remains formed the subject of an interesting discourse by Rev. H. Seeley; after which Prof. Morris, in the Geological Lecture Theatre, delivered an address on the geology of the country around Cambridge, which was listened to with great interest by a large audience, who passed a very cordial vote of thanks to the Professor for his lecture. The afternoon was devoted to a visit to the "coprolite workings" and other excavations at Barnwell. Proceeding along the banks of the Cam a fine section of Pleistocene deposits yielding mammaliferous remains and the usual species of mollusca was reached. This exposure exhibited some very fine examples of false bedding, and many granite and other boulders from the drift were here seen. A very extensive excavation in the Gault here capped by a thin deposit of Upper Greensand lower chalk was next visited. The Gault, excavated for brick making purposes, is exposed to a depth of seventy or eighty feet, and from the evidence of well-sinkers it is probably from 150 to 200 feet thick. Fossils are rarely met with in the Gault clay at this place, though in other localities this formation is very fossiliferous. Lying on the Gault at its junction with the Upper Greensand beds before mentioned occurs the stratum containing the phosphatic nodules or "Coprolites" for which this locality is famous, and which, from another locality, were first noticed as being valuable for agricultural purposes by Prof. Henslow. At a short distance from this excavation the coprolite workings are found on all sides. Indeed, the whole of the land in the neighbourhood is being systematically explored for these valuable nodules which lie at an average of six or seven feet from the surface. One field after another is taken in hand, the coprolite bed of about twelve inches in thickness is taken out, the soil is carefully replaced on the surface, and the field is once again ready for tillage. The "coprolites" are washed by horse power to remove the sand and loam in which they are imbedded, and they are then ready for conversion into manure. A considerable number of fossils, chiefly Brachiopods, were obtained. The party returned to Cambridge, and in the evening were most hospitably entertained at St. John's College by the Rev. T. G. Bonney. On the following day Upware, between Cambridge and Ely, was visited. At this place, situated in the fens and near to the river Cam, very interesting sections have been exposed in consequence of the search for "coprolites." The Gault, which has become very thin, has been cut through and Lower Greensand strata reached. In the Lower Greensand, as at the top of the Gault, a bed abounding in the so-called coprolites is found, and this bed contains characteristic Lower Greensand fossils, together with several new species of Brachiopods described by Rev. J. F. Walker, B.A., F.G.S. Cropping out within a very short distance of this exposure of Gault and Lower Greensand is a remarkable calcareous rock full of corals, which has hitherto been called Coral Rag, but which Rev. Harry Seeley, who has paid great attention to the strata of this district considers to be of Kimmeridgian age, and to which he has applied the name Upware Limestone. This rock is underlain by "Ampthill clay," which would appear to be in this district the equivalent of the Coral Rag of Oxfordshire, Gloucestershire, Dorsetshire, &c. The Brachiopods in the Lower Greensand coprolitic bed are abundant, especially *Terebratula sella*, *Terebratula prælonga*, and *Waldheimia* (*Terebratula*) *Davidsoni*. The next excursion of the Association will be to Belvedere and Erith on Saturday next, and during May visits will be paid to Oxford, Grays in Essex, and Yeovil in Somersetshire.

Anthropological Institute, April 17.—Sir John Lubbock, Bart., president, in the chair. Messrs. Marsden Gibson, Adam Murray, Charles Rooke, and Thomas Davey, were elected members. Mr. F. G. H. Price exhibited a pick made from the antlers of the red deer. Mr. Charlesworth exhibited an ancient Mexican flake of obsidian, an obsidian core, and a Mexican mirror of iron pyrites.—A paper by Dr. W. H. J. Bleek was read on the position of the Australian Languages. After pointing out the discovery, made by Sir George Grey, that the languages spoken throughout the southern portion of the Australian Continent were derived from one common stock, the author proceeded to inquire what relationship they bore to other languages. It was shown that in structure they were diametrically opposed to Polynesian languages; that they had remarkable resemblances to the Drâvidian or South-Indian languages, and should be placed with the latter in the same class. The author gave a comprehensive sketch of the characteristics of the Turanean languages, their modifications and varieties. From the linguistic point of view Dr. Bleek had arrived at the conclusion that the Australian native was, probably, mainly a degenerate offspring of the South-Indian race, and it was possible that the latter might have some admixture of negro blood, although their physical features would not altogether bear out that conclusion. It was not improbable that some portion of the negro race occupied the tropical districts of India. It would appear from a comparison of the religious customs and observances of the past with those of the present time among the Australian aborigines that those people had fallen from a higher civilisation; and that conclusion would seem to be borne out by a consideration of the artificial nature of their weapons, their knowledge of the art of spinning, the peculiar system of castes existing among them, and from other circumstances tending to confirm that view. It was not too much to say that their having been spread in small numbers over a vast continent produced almost necessarily with them, as with many European settlers in new countries, the loss of many of those acquirements of civilisation which they had original possessed.—The Rev. G. Taplin contributed "A comparative table of the Australian languages."—Mr. C. S. Wake read a paper on the mental characteristics of primitive man, as exhibited in the Aborigines of Australia. With reference to the subject of religion the author maintained that as the aborigines could not be said to have any worship at all the argument that they had been derived from inhabitants of the temperate zone was not of any value. That the Australian aborigines did possess certain points of affinity with other races was, in his mind, unquestionable. Those points of affinity, however, did not prove that the Australians had fallen from a higher state of civilisation, or that as a race they had been derived either from Southern India or from Northern Asia. A race, whatever degradation it might undergo, could never lose all trace in its social condition of that which it once possessed, and sink back to the exact state in which it must have been when it first emerged from a condition of barbarism.

Mathematical Society, April 13.—Mr. W. Spottiswoode, F.R.S., president, in the chair. Mr. C. J. Monro, B.A., late Fellow of Trinity College, Cambridge, was proposed for election, and the following gentlemen were elected members:—The Hon. J. W. Strutt, Major Frederick Close, R.A., and Mr. James Stuart, Fellow and Tutor of Trinity College, Cambridge. —The President briefly alluded to the loss the society had recently experienced by the death of its first President, the late Prof. De Morgan. Dr. Hirst, who had been intimately associated with Mr. De Morgan, when both were Professors in University College, gave a sketch of the work done by the deceased professor, especially dwelling upon the originality and acuteness displayed in all his writings, instancing, in particular, his "Double Algebra," his work on the "Differential and Integral Calculus," and his "Formal Logic." The speaker also dwelt upon the warm interest he had taken in the society from its first establishment, which led him to accept the office of first President, and to deliver the inaugural address, and then proceeded to pay a cordial tribute to his personal character. In conclusion, Dr. Hirst stated that Mr. De Morgan's valuable and unique collection of curious works bearing upon the "History of Mathematics," greatly enriched by the owner's own numerous and characteristic quotations, was, he believed, to be disposed of. Several members present expressed their wish that the collection might not be dispersed, but be secured in its entirety for the London University or for the British Museum.—Prof. Crofton, F.R.S., then explained his diagrams in illustration of the "Stresses in Warren and Lattice Girders." Prof. Henrici and Mr. Merrifield, in their remarks on the communication, drew attention to the fact that Mr. Crofton had been anticipated in his constructions in a work by K. Culmann, "Die Graptische

* Communicated by Prof. Morris.

Statik" (1866), who had not only treated this particular matter in a freer manner, but applied his methods to a much wider range of subject. Prof. Henrici further illustrated the subject of the communication by a very simple and ingenious construction.—Prof. Cayley, V.P, followed with a brief sketch of the contents of his third memoir on "Quartic Surfaces."

Institution of Civil Engineers, April 18.—Mr. Charles B. Vignoles, F.R.S., president, in the chair.—"On the Archimedean Screw Propeller, or Helix, of Maximum Work," by Sir F. C. Knowles, Bart. In considering the construction and action of the Griffiths' Screw Propeller, the author of this memoir was struck by the fact that the blades worked in great part in the lateral streams of the water, and had no action in the dead water behind the sternpost, where power applied ought to be the most efficient. Again, in the common screw propeller at all points near the axis, the power was almost wholly employed in churning the water, and in producing vibration by alternately lifting and depressing the stem, which no doubt induced Mr. Griffiths to limit the extent of his blades to points without that space. These considerations led to an endeavour to devise some form of blade which should be free from that imperfection, and yet on the whole possess the feathering property of the Griffiths' screw. But no particular form presenting itself which on principle could be pronounced preferable to any other form, the author decided upon proceeding to an *a priori* solution of the question, and assuming the existence of some best form, he was ultimately led to propose this problem: "What is the form of the surface of the screw propeller of which the 'work done' is the greatest possible?" The complete solution of this problem was the subject of the paper, and the following was an outline of the methods employed, and of the results obtained. Referring the required surface to three rectangular co-ordinates x, y, and z, one in the axis of rotation, the other two in the plane of rotation, the author first obtained a general expression for the total "work done" by the blade in propelling the ship, in the form of a double integral in terms of the co-ordinates x and y and of the partial differentials of z with respect to each of them, of the speed of rotation of the blade, and lastly of the speed of the ship. As this integral was to be a maximum for all points of the surface sought, it must be treated by the known methods of the Calculus of Variations. This done, an equation of condition was obtained, which, by the performance of the operations indicated by the symbols, led to an equation involving two factors, each factor being a partial differential equation between the three co-ordinates of the surface. The first of these being integrated gave for its solution the whole family of ordinary helices which were the surfaces of *least* work. The second factor was the differential equation of the required surface, the treatment of which was given in the paper *in extenso.* It led at once, and very simply, to an equation analogous to that of the common helix $\left(\tan.\ \theta = \frac{a \tan.\ a}{r}\right)$ namely, $\tan.\ {}^2\theta = \frac{a \tan.\ 2a}{r}$

From this it was at once deducible, that the surface of the blade at the axis cut the plane of rotation at an angle of 45°, while the common helix cut it at 90°, and therefore acted powerfully in the dead water to propel the ship, just where the common helix had no propulsive power. It was proposed to call this surface the hemi-helix, or hemi-angular helix.—The paper then proceeded to determine the pressure of this blade upon the vessel in the direction of the keel, and thence the whole circumstances of the ship's motion. It was found that there was what was called "a slip," as in the case of the common helix. The author objected to this term, as involving a fallacious theory of the action of the screw,—in effect a denial of the equality of action and reaction. In order fully to expose the fallacy, the motion of a ship impelled by the common helix as a case of variable motion in a resisting medium was investigated, and, from the identity of the conditions and of their algebraical expressions it was proved that what was called "slip" of the screw was neither more nor less than "the ratio of the difference between the velocity which the ship would have in a non-resisting medium and its actual terminal velocity in the water to the former velocity." It was proposed, therefore, to substitute for this objectionable expression the term "ratio of resistance," or "relative resistance," as accurately representing the real phenomena, and measuring the efficiency of the given screw in propelling the given vessel. The author was thus further enabled to explain what had been called "negative slip," and to assign its origin to the joint action of wind and steam, it being impossible in the case of steam alone. In the course of the discussion, objection was taken to the fundamental principles enunciated in the paper; although those principles used to be almost universally promulgated in mathematical treatises of reputed authority, and were commonly even now relied on as the basis of mathematical reasoning, by those whose investigations and experimental researches had not obliged them to detect their unsatisfactory character. Reference was made, in the first place, to what might be called the very foundation of the author's deductive process,—the proposition that when a plane moved obliquely through a fluid at a given velocity, the normal pressure on its surface was as the square of the sine of the angle of obliquity. In the second place, to the hypothesis that when the true law of pressure on a plane thus moving had been in any way determined, the local pressure on each unit of surface of a curved surface moving through a fluid could also be determined, by applying that law to the unit in virtue of the angle presented by its tangent plane to the line of motion. And thirdly to what appeared to be a misconception of the dynamical relations, or inherent conditions of the slip of the propeller.

Zoological Society, April 18.—Dr. E. Hamilton in the chair. The Secretary read a report on the additions that had been made to the society's collection during the month of March, 1871. Amongst these particular attention was called to a young male specimen of the Cape hunting dog (*Lycaon pictus*), a species which had been deficient to the society's collection since 1855.—Mr. H. E. Dresser exhibited a specimen of the American yellow-billed cuckoo (*Coccyzus americanus*), recently killed in England, and Sir Victor Brooke a specimen of the Esquimaux curlew (*Numenius borealis*), lately killed in Ireland.—Prof. Owen, F.R.S., read a paper on the dodo (*Didus ineptus*), containing notes on an articulated skeleton of this extinct bird, recently prepared from bones exhumed by Mr. Clark in the Mauritius, and now exhibited in the Ornithological Gallery of the British Museum.—A paper was read by Mr. Thomas Davidson, F.R.S. (communicated by Mr. J. Gwyn Jeffreys), containing a revised account of the recent Brachiopoda dredged by Mr. Arthur Adams in the Japanese Seas.—Messrs. Sharpe and Dresser pointed out the characters of a new form of long-tailed titmouse, which occurs in Southern Spain and in Italy, and which they proposed to call *Acredula irbii.*—Mr. R. B. Sharpe read the second part of his "Contributions to the Ornithology of Madagascar," in which was given an account of a collection of birds recently made by Mr. Crossley in that island. Among these were a specimen of a new swift proposed to be called *Cypselus gracilis.*—A communication was read from Dr. A. Günther, F.R.S., containing the description of a new form of percoid fishes from the Macquarie River, Australia, which he proposed to call *Ctenolates macquariensis.*—A communication was read from Dr. James C. Cox, containing descriptions of some new species of land and marine shells, from Australia and the Southern Pacific.—Two communications were read from Mr. J. Brazier. The first contained descriptions of some new land-shells from New South Wales—the second notes on some species of shells recently described by other authors from the Australian region.

Chemical Society, April 20.—Prof. Odling, F.R.S., vice-president, in the chair. The following gentlemen were elected fellows: C. C. Grundy, J. B. Lee, G. Sutcliffe, W. Ward. Mr. C. Haughton Gill read a paper on some saline compounds of cane sugar. The author having succeeded in obtaining a crystalline compound of sodic chloride with cane sugar, mixed a number of sugar solutions with different salts and set them to crystallise spontaneously, or when no crystals were obtained by these means a more rapid evaporation was tried. The salts employed were the chlorides of potassium, sodium, lithium, and ammonium; the bromides of potassium and sodium, and the iodides of potassium, sodium, lithium, and ammonium. None of the potassium salts gave compounds of a definite composition. The sodium salts gave much better results; there were two varieties of sodic chloride compounds formed, constituted respectively $2\ (C_{12}H_{22}O_{11})\ .\ 3\ Na\ Cl\ .\ 4\ H_2O$ and $C_{12}H_{22}O_{11}\ .\ Na\ Cl\ .\ 2\ H_2O$; the solutions containing sodic bromide gave crystals of the composition $C_{12}H_{22}O_{11}\ .\ Na\ Br\ .\ 1\frac{1}{2}\ H_2O$, they were probably not quite pure; the sodic iodide combination, $2\ (C_{12}H_{22}O_{11})\ .\ 3\ NaI\ .\ 3\ H_2O$, formed very fine crystals. The mixture containing lithium gave only crystals of pure cane sugar. The constitution of the sodic iodide compound makes it seem probable that the true molecular weight of cane sugar should be represented by $C_{24}H_{44}O_{22}$. The measurements of the crystals mentioned in Mr. Gill's paper were executed by Prof. Miller.

PARIS

Academy of Sciences, April 3.—The account of this sitting is printed in the *Journal Officiel*, the first time since the beginning of the investment of Paris. The account was signed and written by M. Henry de Parville.—M. Simon Newcomb was present at the sitting, and read a communication on the perturbations in the motion of the moon, owing to the attraction of the different planets. The American astronomer proposes to solve this great question, by a new method. The problem is to be solved by one hundred and fifty different equations! M. Newcomb admits it is quite impossible to solve it, without some startling simplification. The present communication is to show the Institute the way through which the author hopes to realise these simplifications. It is not the final work, which, if it is successful, will prove M. Newcomb has made a great analytical discovery. But in such a matter *experience passe science*. M. Delaunay offered no remark on the subject, although he has devoted to it the greater part of his life. He remains on the defensive. — M. Robin, the celebrated microscopist, handed a note on the analysis of blood taken from a man attacked by scurvy. The author shows, from observations made at Necker and Gros Caillou Hospitals, that under these circumstances many white globules are mixed in the blood. But leucocithemic having been observed in other affections, it cannot be considered as a specific character of that dangerous affection so common in besieged towns, and which was frequently observed in Paris towards the end of 1870.

The candidates for the great prize for curing cholera are not easily frightened by the civil war. The premium of 4,000*l.*, given by the late M. Breaut, is worth incurring any risk. A M. Drouet sends a note giving the true cure. The process is simple enough. It is sufficient to cover the stomach of the patient with the film of a collodion, prepared by a mixture of ordinary collodion and castor oil. This collodion film is a specific against hysterical fits, typhoid fever, &c. It must be admitted that the total stopping of all perspiration may be considered as being of some help in different affections. The process may be considered as worth a trial at least, under some peculiar circumstances.—It was stated that the Institute will not interrupt its sittings at any price. If there remains only a single member, that member will sit in order to keep a regular register of communications addressed to the learned company. It is the only means for securing intellectual prosperity of scientific discoveries, and it cannot be stopped even by Communalists. We have no news of the sitting of the 10th.

BOOKS RECEIVED
